Therapy with the anti-tumor necrosis factors (TNF) infliximab and etanercept [161-163] was of no benefit and potentially harmful in newly diagnosed GCA. Tocilizumab, an IL-6 receptor alpha inhibitor, induced remission and reduce glucocorticoid requirements in patients with refractory GCA [44, 164-167]. A multicenter RCT underway at the time of the writing of this chapter in 2015 has been concluded [168]. Tocilizumab, received weekly or every other week, combined with a 26-week prednisone taper, was superior to either 26-week or 52-week prednisone tapering plus placebo with regard to sustained CS-free remission in patients with GCA. Longer follow-up is necessary to determine the durability of remission and safety of tocilizumab. Sustained remission at week 52 occurred in 56% of the patients treated with tocilizumab weekly and in 53% of those treated with tocilizumab every other week, as compared with 14% of those in the placebo group that underwent the 26-week prednisone taper and 18% of those in the placebo group that underwent the 52-week prednisone taper ($P < 0.001$ for the comparisons of either active treatment with placebo). The cumulative median prednisone dose over the 52-week period was 1862 mg in each tocilizumab group, as compared with 3296 mg in the placebo group that underwent the 26-week taper ($P < 0.001$ for both comparisons) and 3818 mg in the placebo group that underwent the 52-week taper ($P < 0.001$ for both comparisons). Serious adverse events occurred in 15% of the patients in the group that received tocilizumab weekly, 14% of those in the group that received tocilizumab every other week, 22% of those in the placebo group that underwent the 26-week taper, and 25% of those in the placebo group that underwent the 52-week taper.

The impact of aspirin use on ischemic cranial complications was demonstrated in GCA as a basis for management of GCA [169, 170], however an impact was not shown in retrospective cohorts [171-173].

CONCLUSION

GCA is a common, serious and treatable vasculitis that affects older adults. Rapid access and management care pathways ensure the early referral of untreated suspected patients for

readily available TAB especially warranted in those with low to moderate probability of disease, and appropriate primary and secondary care to prevent excess morbidity and mortality associated with empiric and often unwarranted high-dose CS therapy. Published guidelines for GCA diagnosis and management need to be rigorously examined to assess the impact of CRP, TAUS signs, large vessel imaging, and TAB in any given patient, especially those who warrant empiric high dose CS due to impending visual loss. Moreover, guidelines need to reflect a unified definition of clinical relapse. Studies assessing the link between clinical symptoms, inflammatory markers, imaging techniques and mimicking conditions will be very valuable. Finally, long-term vascular complications are increasingly recognized in GCA, and this is blurring the margin between atherosclerosis and vasculitis, which may improve our understanding of both these conditions [65]. Biological agents including tocilizumab are emerging as effective and safe CS-sparing therapy in treating GCA

ABSTRACT

There have been significant advances in the understanding of the vasculitides in the past several years leading to more precise classification and nosology. Ophthalmologic manifestations may be the presenting feature of and a clue to the diagnosis of vasculitis, or develop in the course of the illness due to a common disease mechanism. Precise diagnosis and prompt treatment prevents short and long-terms ophthalmologic sequela.

Keywords: neuro-ophthalmology, ophthalmology, vasculitis, CNS

INTRODUCTION

Vasculitis is a term used to characterize a spectrum of diseases associated with vascular inflammation. Ophthalmologic manifestations may be the presenting features of primary and secondary systemic vasculitis and a clue to early diagnosis to prevent ischemic vascular sequela. Unrecognized and therefore untreated, the ophthalmologic and neuro-ophthalmologic features can be catastrophic with irreversible loss of function particularly when visual involvement coincides with vasculitic brain infarction, hemorrhage, and aneurysm formation or ischemic involvement of the optic nerve or surrounding orbital structures. This chapter

* Corresponding Author's Emails: david.younger@nyumc.org; <http://www.davidsyounger.com>.

considers the ophthalmologic aspects of primary systemic vasculitis and primary central nervous system vasculitis (PCNSV) in children and adults. Galetta [1] has reviewed the neuro-ophthalmologic aspects of vasculitides.

CLASSIFICATION OF VASCULITIS

Two Chapel Hill Consensus Conferences (CHCC), one in 1994, and the other revised in 2012 [2, 3], provided consensus on nosology and definitions for the commonest forms of vasculitis in adults based upon the caliber of vessels involved. The Pediatric Rheumatology European Society (PRES) and the European League against Rheumatism (EULAR) proposed specific classification criteria for the commonest childhood vasculitis syndrome [4] based upon vessel size similar to the CHCC nomenclature [3]. The EULAR, PRES, and the Pediatric Rheumatology International Trials Organization (PRINTO) defined the clinical, laboratory and radiographic characteristics for several childhood systemic vasculitides in a validated classification of pediatric vasculitis [5]. There is a continuum of vasculitic disorders with some occurring exclusively in childhood or in older adults, and others across the age spectrum although with differing epidemiology, clinical and laboratory manifestations, and response to treatment. Large vessel vasculitis (LVV) includes giant cell arteritis (GCA) and Takayasu arteritis (TAK) affects the aorta, its major branches and analogous veins. Medium vessel vasculitis (MVV) includes polyarteritis nodosa (PAN) and Kawasaki disease (KD) with typical involvement of main visceral arteries and veins and initial branches. Small vessel vasculitis (SVV) comprises disorders with vasculitis of intraparenchymal arteries, arterioles, capillaries, veins and venules, and disease pathogenesis related to anti-neutrophil cytoplasmic antibody (ANCA) production, or the formation of immune complexes (IC). The category of ANCA-associated vasculitis (AAV) includes granulomatosis with polyangiitis (GPA) (Wegener granulomatosis type), eosinophilic granulomatosis with polyangiitis (EGPA) (Churg-Strauss syndrome type), and microscopic polyangiitis (MPA) (microscopic polyarteritis), while vasculitic disorders associated with IC include hypocomplementemia urticarial vasculitis (C1q), cryoglobulinemic vasculitis (CV), and IgA vasculitis (IgAV) (formerly Henoch-Schönlein purpura [HSP]). Vasculitis without a predominant vessel size and caliber, respectively from small to large, involving arteries, veins and capillaries, comprises the category of variable vessel vasculitis (VVV), characteristic of Behçet disease (BD) and Cogan syndrome (CS). The category of single-organ vasculitis (SOV), that involves arteries or veins of any size in a single organ without features to indicate that it is a limited expression of a systemic vasculitis, is typified by central nervous system (CNS) vasculitis.

LARGE VESSEL VASCULITIS

Giant Cell Arteritis

This granulomatous LVV involves cranial branches of the arteries arising from the arch of the aorta. It occurs exclusively in individuals older than age 50 years, with an annual incidence of 15-25 persons per 100,000, with higher rates in Caucasian individuals compared

to African Americans, and among women compared to men in a ratio of 2 to 3:1 [6-9]. The ACR 1990 criteria for the classification of GCA [10], designed for use in investigative studies to help distinguish GCA from other types of vasculitides, are not useful for making the diagnosis in individual patients [11]. Five criteria were selected by the ACR [10] from which three or more in a given patient was associated with a sensitivity of 93.5% and a specificity of 91.2%, from among the following: age equal to or greater than 50 years at disease onset, new localized headache, temporal artery tenderness or decreased temporal artery pulse, elevated erythrocyte sedimentation rate (ESR) to 50 mm/hour or more, and vascular tissue biopsy sample showing necrotizing arteritis with predominance of mononuclear cells infiltration or granulomatous multinucleated giant cell inflammation. The histopathology of biopsy-positive GCA is typified by vessel wall infiltration by mononuclear cells, CD4+ T-cells, activated macrophages and multinucleated giant cells, that latter of which form granulomas close to the internal elastic lamina of involved vessels in up to one-half of specimens [12].

Visual loss due to anterior ischemic optic neuropathy (AION), which results from occlusion of short posterior ciliary arteries that supply the optic nerve head, is the commonest ocular symptom in GCA with a frequency that varies from 10% to 60%. Other causes of visual loss include vasculitic involvement of the choroid, posterior optic nerve and retina [13]. Visual loss may be partial, complete, or permanent, and is preceded by amaurosis fugax in 44% of patients [9]. A prospective study of 170 patients with biopsy-confirmed GCA [14] noted ocular involvement in 85 (50%) patients, including visual loss present in 83 (97.7%), amaurosis fugax in 26 (30.6%), eye pain in seven (8.2%), and diplopia in 5 (5.9%). Ocular ischemic lesions consisted of arteritic AION in 69 (81.2%), central retinal artery and cilioretinal occlusions each in 12 (14.1%), the latter after satisfactory fundus fluorescein angiography (FFA); as well as, posterior ischemic optic neuropathy in 6 (7.1%), and ocular ischemia in 1(1.2%) patient. Those with ocular involvement were significantly older than the patients without ocular involvement, and surprisingly less likely to have prominent constitutional and systemic symptomatology. Among 42 other patients from Olmsted County Minnesota studied by Huston and coworkers [15], visual symptoms preceded the clinical and histopathologic diagnosis of GCA in 15 (40%) patient, of which blurred vision was most common so noted in 6 (19%) of patients, followed by diplopia in 5 (12%), transient vision loss in 5 (12%), permanent partial loss in 4 (10%), and permanent complete loss in 3 (10%) patients. A followup Olmsted County cohort twenty-five years later totaling 168 patients with GCA by Nuenninghoff and colleagues (16) found visual disturbances overall at presentation in 16 (9.5%) patients, and at the time of diagnosis in 37 (22%) patients, of whom 14 (8.3%) patients had transient vision loss, 18 (10.7%) had permanent vision loss, and 14 (8.3%) had diplopia.

Of 18 patients with varying visual loss and occult GCA [17], amaurosis fugax was noted in 6 (33.3%), diplopia in 2 (11.1%), and eye pain in 1 (5.6%) patient. Ocular ischemic lesions included AION in 17 (94.4%) patients, and central retinal artery occlusion and cilioretinal artery occlusions each in 2 (11.1%) after FFA. The authors [17] concluded a high index of suspicion for GCA for patients older than 50 who develop amaurosis fugax, visual loss, or AION in the absence of constitutional and systemic symptoms (Figure 1).

Ocular involvement was more common in patients with GCA without large vessel vasculitic involvement according to Prieto-González and colleagues [18] who studied 40 patients with newly diagnosed biopsy-proven GCA by computed tomographic (CT) imaging to define LVV involvement of the aorta and its tributaries. Ocular involvement was noted

more often in those with LVV aortic involvement than without (15% versus 54%). Conversely, ischemic events were more common in those without than with evidence of LVV aortic involvement by CT-imaging (54% vs. 22%). The authors postulated a spectrum of GCA disease with cranial arteritis manifested by ocular symptoms, headache, and jaw claudication at one end and predominant LVV at the other.

Figure 1. Patient with giant cell arteritis and brainstem stroke demonstrating left gaze paresis.

The incidence and severity of visual loss and ocular involvement appears to depend upon the promptness of diagnosis and treatment. Although AION is the commonest cause of visual loss in GCA, only 5.7% of patients with AION will have GCA making it critical to distinguish arteritic from non-arteritic AION in suspected patients [19]; FFA are a critical tool in this distinction. The appearance of posterior ciliary artery occlusion is diagnostic of arteritic AION, while non-arteritic AION is almost always due to a fall in perfusion pressure in the peripapillary choroid and not from primary ciliary artery occlusion (20). One other finding that supports the diagnosis of arteritic AION in up to one-half of affected patients presenting with visual symptoms is chalky-white optic disc swelling [21]. A small disc and cup may be associated with both arteritis and non-arteritic AION, while a normal or large cup is highly suggestive of an underlying arteritic process [22]. Color Doppler imaging of the central retinal and short posterior ciliary arteries is helpful in distinguishing GCA from non-arteritic AION. Ho and colleagues [23] compared color Doppler flow imaging in patients with GCA to matched control subjects revealing reduced central retinal and short posterior arterial mean flow velocities and increased vascular resistance.

The mainstay of treatment for GCA is corticosteroids however the exact dosing regimen and mode of administration depends upon the presence of visual involvement at the time of diagnosis. Patients with unilateral complete loss, evidence of fellow eye involvement, and amaurosis fugax are treated with 1 gram of intravenous corticosteroids every 6 to 8 hours followed by the oral prednisone. Salvarani and colleagues [24] employed 40 mg to 60 mg oral prednisone for GCA, and intravenous methylprednisolone 1g per day for 3 day for those with recent or impending visual loss. The addition of low dose aspirin to corticosteroid therapy was beneficial in preventing cranial ischemic complications including acute visual loss and cerebrovascular complications of GCA than steroids alone. Patients treated with aspirin and

corticosteroids are five-fold less likely to experience cranial ischemic complications than those who received corticosteroids alone [25]. Aiello and colleagues [26] noted visual improvement in 15% of eyes after commencing therapy for GCA and estimated a probability of further visual loss developing of 1% in the absence of a defined visual deficit, compared to 13% when an established deficit was ascertained. Danesh-Meyer and colleagues [27] evaluated the incidence and extent of visual recovery of 34 patients with biopsy-proven GCA treated with high dose systemic corticosteroids noting that 27% of eyes suffered loss of visual acuity by two or more lines within one week of starting corticosteroid treatment, while 15% of eyes so treated showed an improved visual acuity of 2 or more lines. Of the 15% of eyes that showed an improvement in visual acuity, none showed further improvement in visual fields or color vision, leading the authors [27] to conclude that the improvement in visual acuity may reflect learning to view eccentrically. Liu and colleagues [28] investigated 45 patients with biopsy-proven GCA, 25 of whom were treated with intravenous methylprednisolone, and 20 treated with oral prednisolone. Visual loss remained unchanged in 49% so treated, worsened in 17%, and improved in 34%, defined as visual acuity improvement of two or more lines and final acuity greater than 20/80. Fellow eye involvement more often occurred in patients receiving oral corticosteroid therapy compared to those receiving intravenous therapy. Similarly, visual acuity was more likely to improve after a course of intravenous treatment than oral therapy (39% versus 28%).

Takayasu Arteritis

This systemic necrotizing LVV is characterized by thrombosis of the vessels arising from the aortic arch. TAK predominantly occurs in young Japanese females, typically arising before the age of 40, in a 9:1 female to male ratio [29-31]. The incidence of TAK is estimated to be between 0.4 to 2.2 per million people, [32, 33] with higher rates in South East Asia, Africa and South America [34, 35].

The ACR [36] selected six criteria for the classification of TAK, from which three or more in a given patient were associated with a sensitivity of 90.5% and a specificity of 97.8%, from among the following: age less than or equal to 40 years, claudication of an extremity, decreased brachial artery pulse, greater than 10 mmHg difference in systolic blood pressure between arms, a bruit over the subclavian arteries or the aorta, and arteriographic evidence of narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities. Although the histopathology of TAK is not included as part of the ACR criteria [36], it may aid in the diagnosis, and it is characterized by an acute periarteritis with extensive cellular infiltration, necrosis of the media, and intra-arterial thrombosis [37]. Ocular features not formally part of the criteria of TAK occur in 35% to 68% of patients [38-40], typically due to ischemia and hypoperfusion resulting from occlusive arteritis of the aortic arch branches, while those arising in the setting of hypertension result from vasculitic renal artery involvement.

The commonest ischemic ocular manifestation of TAK is retinopathy, first described by Takayasu [41] who noted peculiar fundus changes consisting of dilated vessels around the optic disc due to arteriovenous (AV) anastomoses in female patients without a palpable radial pulse. Less common ocular ischemic manifestations include anterior ischemic optic

neuropathy (AION), central retinal artery occlusion, and ocular ischemic syndrome [29, 42]. The retinal changes in TAK vary in symptomatology and severity depending on the location of carotid artery involvement, the rate and duration of ocular vascular hypoperfusion, and the presence of collateral blood supply to the eye [38].

Uyama and Asayama [30] studied 80 patients with TAK noting that 38 (48%) of patients had involvement of the aortic arch and stenosis or occlusion of its proximal branches denoting type I TAK; 25 (31%) patients had type II TAK characterized by involvement of the whole aorta and its branches, and 16 (20%) had type III TAK characterized by involvement of the descending thoracic and abdominal aorta and its branches. Altogether, 38 (100%) of patients with type I TAK had retinopathy. Uyama and Asayama (30) classified retinopathy into stages 1 to 4 wherein 20 (53%) patients with stage 1 had dilations of small vessels; 12 (32%) patients with stage 2 disease had microaneurysm formation; 3 (8%) patients each with either stage 3 or 4 disease, respectively manifested AV anastomoses or ocular complications of vitreous hemorrhages, proliferative retinopathy and vision loss. The authors attributed the retinal vascular changes to decreasing blood flow in the retinal vasculature noting decreased intraocular pressure with disease progression. In contrast to type I TAK, hypertensive fundal changes predominated in patients with type III disease with 12 (86%) demonstrating hypertensive changes occurring in the fundus, and 2 (14%) manifesting hypertensive retinopathy.

Chun and colleagues [38], who reviewed medical records and FFA of 156 eyes from 78 patients with TAK, noted that the commonest ocular symptoms were subjective decrease of vision in 23 (29.5%) patients; amaurosis fugax in 20 (25.6%) patients; ocular pain in 9 (11.5%) patients; and metamorphopsia in 3 (4%) patients. Among 13 cases of retinopathy, 69% occurred in patients with TAK involving primarily the aortic arch and its branches, and among 25 patients with hypertensive retinopathy, 18 (72%) patients had involvement of the thoraco-abdominal aorta, its branches, and the aortic arch. Thus, patients with retinopathy were more likely to have carotid artery or aortic arch involvement, while those with hypertensive retinopathy were more likely to have involvement of the descending aorta.

The importance of staging retinopathy was highlighted by Chun and coworkers [38] who demonstrated that visual acuity (VA) dramatically worsened as patients progressed from stage 3 to stage 4 retinopathy. The best corrected VA in patients with Stage 1 to Stage 3 retinopathy ranged from 20/15 to 20/30, while those with stage 4 disease had VA ranging from 20/200 to hand motion alone. Causes of impaired VA in such patients included total cataract in 4 patients, neovascular glaucoma in 2 patients, vitreous hemorrhages in 1 patient, tractional retinal detachment in 3 patients, optic atrophy in 3 patients, and AION in 1 patient. Peter and coworkers [29] demonstrated an association between VA and retinopathy, noting a causal relation between uncorrected refractive error among 18 patients that was due to a cataract in 6 (33%) patients, grade 4 retinopathy in 4 (22%) patients, optic atrophy in 2 (11%) patients, hypertension with retinal detachment, longstanding papilledema, and retinal pigment changes of the fovea, and a posterior capsular opacity each in 1 (6%) patient. Although there was no correlation of patient age, duration of symptoms, history of limb claudication, presence of a carotid bruit, hemiplegia, or increased ESR or C-reactive protein (CRP) levels with the development of retinopathy, retinopathy was more frequent in those with significantly lower blood pressures and non-recordable right upper limb blood pressures than in patients without retinopathy.

Ocular symptoms are typically a late manifestation of disease, with ophthalmic evaluation occurring on average 55 ± 69 months after disease onset. [29]. An ocular ischemic syndrome was the initial disease manifestation of TAK in three reported patients ranging in age from 14 to 42 years, of subacute or chronic progressive onset (43-45) , in whom vascular imaging was crucial in the etiological diagnosis.

FFA is an important tool in determining the extent of ocular involvement in TAK [46], and when compared with indirect ophthalmoscopy in 31 eyes with TAK showed no additional changes in ten eyes without retinal vein dilation on indirect ophthalmoscopy. However, of 7 eyes with dilated retinal veins, FFA revealed additional abnormal findings such as microaneurysms, arteriovenous shunts, retinal neovascularization, and avascular areas important in grading the stages of retinopathy. Chun and colleagues (38) noted prolongation of arm-to-retina circulation time in all 21 (100%) eyes with retinopathy while 14 (67%) patients had delayed arteriovenous filling time. Similarly Uyama and Asayama [30] noted that arm to retinal time was delayed by 20 seconds on FFA in patients with retinopathy.

Kerr and colleagues [31] noted a 60% response rate to corticosteroids alone among 60 patients with TAK with an estimated time to remission of 22 months. In the steroid resistant patients, cytotoxic therapy employing methotrexate and cyclophosphamide induced remission in another 40% of patients. Jales-Neto and coworkers [47] found that combination corticosteroid and immunosuppressive therapy led to disease remission in 55% of adult patients, and in 24% of patients less than age 18 years. Among four patients with TAK treated with corticosteroids described by Ishikawa [48], one improved from stage 3 to stage 2 TAK, while another patient developed unilateral blindness, and two others, were stable. Pan-retinal photocoagulation is an adjunctive therapy used to treat cases of severe retinal ischemia [38], whereas antiplatelet agents reduced the frequency of arterial ischemic events in patients with TAK [49]. So noted and treated promptly with corticosteroids, the inflammatory process underlying ocular manifestations may lead to improvement, however arterial stenoses may require bypass surgery [50, 51].

MEDIUM VESSEL VASCULITIS

Polyarteritis Nodosa

This systemic necrotizing vasculitis predominantly affects medium-sized arteries with an estimated annual incidence of 1.1 cases per 1,000,000 people in Australia [52] to 31 per 1,000,000 people in Sweden [53], and 77 per 1,000,000 people in the hepatitis-B virus (HBV) endemic area of Alaskan Eskimos [54]. The disorder is slightly more prevalent in males, with a male-to-female ratio of 1.7 to 1.9:1, and most predominant in patients 40 to 60 years of age, with an average age at onset of 47 years [55, 56]. The 2012 Revised CHCC [3] distinguished PAN from MPA, distinguishing it as a necrotizing arteritis of medium or small sized arteries without glomerulonephritis, or vasculitis in arterioles, capillaries or venules, and unassociated with antineutrophil cytoplasm antibodies (ANCA). The pathologic findings of PAN include hyaline-like necrosis in the media which rapidly spreads to the adventitia and intima, and infiltration by neutrophils, eosinophils, lymphocytes and plasma cells. This is followed later by proliferation of fibroblasts that can thicken the intima and occlude vascular lumina [57].

Although ocular manifestations are not a part of the diagnostic criteria for PAN, they occur in 10% to 20 per cent of patients [58] either due to the direct effects of arteritis that results in vascular ischemia, or as a secondary effect of renovascular hypertension with subsequent retinal edema, transudates, hemorrhages and cystoid body formation [59]. The most common arteries affected are the posterior ciliary arteries and choroidal vessels, which can result in choroidal infarcts and exudative retinal detachments [59]. Conjunctival and anterior uveal involvement has also been reported [60]. Orbital involvement may result in exophthalmos, optic nerve involvement in visual loss, ocular vessel involvement in episcleritis, necrotizing scleritis, and corneal and scleral ulcers [61]. In an analysis of 393 patients with PAN [62], 42 (10.7%) patients had ophthalmologic manifestations of which blurred vision was the most common so noted in 13 of 42 (31%) patients, followed by conjunctivitis in 8 (19%) patients, retinal exudates in 8 (19%) patients, and retinal vasculitis in 7 (17%) patients. Other less common manifestations included uveitis in 5 (12%) patients, episcleritis in 4 (10%) patients, thrombosis in 4 (10%) patients, keratitis and optic neuropathy each in 3 (7.1%) patients, retinal hemorrhages in 2 (5%) patients, and oculomotor nerve palsy in 1 (2%) patient. A study on 348 patients with PAN [63] noted ophthalmologic manifestations in 30 (8.6%) patients, consisting of retinal vasculitis, retinal exudates, or both in 15 (4.3%) patients; conjunctivitis or keratitis in 12 (3.4%) patients, uveitis in 3 (0.8%) patients, and blurred vision in 2 (0.6%) patients. There was little difference in the frequency of ophthalmologic manifestations in those with or without HBV-related PAN, so noted respectively in 10% versus 7% of patients. Moreover, visual symptoms were the presenting manifestation of PAN in several reported patients, including one with thrombocytosis and acute blindness secondary to central retinal vein thrombosis [64], others with visual loss due to retinal vasculitis [59] and bilateral choroidal vasculitis [65], and another patient with dacryoadenopathy [66].

Reports of fundoscopic examination findings in patients with PAN are varied and include papilledema, macular star formation, cotton-wool spots, retinal or subhyaloid hemorrhages, retinal exudates, vascular occlusion of the central retinal artery, and irregularity of the retinal arteries with or without aneurysm formation [59]. Retinal fluorescein angiography may also be particularly helpful in the diagnosis and management of PAN. Acute multifocal choroidal ischemia is a common feature seen on fluorescein angiography in patients with PAN, yet very rare in the general population, presumably because the degree of vasculitis is sufficiently severe to affect the choroid [67]. Other common features on fluorescein angiography in PAN include retinal vasculitis with multiple arteriolar and capillary occlusions [67].

Although there are few studies of the effect of corticosteroid treatment on the ocular manifestations of PAN, Nanjiani [58] reported treatment of bilateral optic neuritis, and circumscribed posterior choroiditis with serous retinal detachment with corticosteroids that improved systemic but not ocular manifestations. Akova and colleagues [68] described responsiveness of a spectrum of ocular findings including scleritis, peripheral ulcerative keratitis, nongranulomatous uveitis, retinal vasculitis, pseudotumor of the orbit, and central retinal artery occlusion in five patients, four of whom responded to combination corticosteroid and cyclophosphamide or azathioprine therapy.

Kawasaki Disease

This medium vessel vasculitis is one of commonest vasculitides in children with incidence rates varying from 8.39 per 100,000 children under age 5 per year in England [69] to 218.6 per 100,000 children under age 5 in Japan [70]. The disease occurs more often in males, with a male to female ratio of 1.3-1.6:1 [71, 72]. KD typically occurs in patients under 5 years of age, with a peak age of onset ranging from 9 to 11 months in Japan [70], and over 12 months in Canada and Britain [73, 74]. There are six diagnostic features of KD, five of which are needed for the diagnosis. They include fever of unknown origin lasting five days or more not responding to antibiotics; bilateral conjunctival hyperemia and indurated edema that spares the limbal region; orolabial lesions; redness and edema of palms and soles followed by fingertip desquamation; an erythematous polymorphous rash; and cervical lymph node enlargement [71].

Ocular involvement in KD is typified by bilateral conjunctival hyperemia and indurated edema that spares the limbal region; and conjunctivitis that occurs in 83% to 92% of patients [74]. The conjunctival lesion typically develops within a day or two of fever-onset and lasts up to several months [75]. Other ocular findings included bilateral injection of the bulbar conjunctiva so noted in up to 89% of patients, bilateral iridocyclitis in 78% of patients, superficial punctate keratitis in 22%, vitreous opacities and papilledema each in 11%, and subconjunctival hemorrhage in 6% of patients. Bulbar conjunctival injection typically occurs first, followed by acute iridocyclitis identified by inflammatory cells in the anterior chamber that reaches a maximum between the fifth and eighth day, thereafter diminishing after one month. Acute bilateral iridocyclitis is more common in children 4 years and older however the severity of iridocyclitis is generally independent of age [76]. Burke and co-workers [77] noted that anterior uveitis was a predominant finding during the acute phase of illness. Other less common ocular findings in KD include disciform keratitis, so noted in a 10-year-old [78] and 11-year-old reported children [79], the latter of who presented with diffuse bilateral non-purulent conjunctival congestion, VA of 6/6 in the right eye and 6/5 in the left eye, and later developed cloudy vision. Ophthalmologic examination revealed that his vision was reduced to less than 6/60 in both eyes and that he had bilateral central stroma edema with localized keratic precipitates. However, fundoscopy showed bilateral disc swelling without evidence of posterior segment inflammation. The latter, also rare, was similarly documented in several patients, including.

Posterior segment involvement in KD was documented in two patients with bilateral vitreous opacities and bilateral optic disc swelling [76], unilateral retinal exudates, macular and disc edema with severe visual loss [80] and in a patient with bilateral inner retinal ischemia diagnosed at postmortem examination [81]. Retinal vasculitis occurs rarely in KD due to selective inflammation of the blood-ocular barrier [76]. Several reported patients underwent FFA for retinal vasculitis, including one with retinal exudation, macular edema, and temporal disc swelling that showed no leakage [82], and another with bilateral acute anterior uveitis, in whom FFA showed disc edema and leakage with localized areas of perivascular sheathing suggestive of periphlebitis and vasculitis [83].

First line therapy for KD includes intravenous immune globulin (IVIg) therapy and aspirin. However corticosteroids and tumor necrosis factor (TNF) inhibitors may be beneficial those who fail to respond to IVIg therapy [84, 85]. A few small series and case reports

showed a favorable response of conjunctivitis and anterior uveitis respond to treatment with corticosteroids and mydriatics [80], IVIg therapy and aspirin [83]. One other patient with disciform keratitis and bilateral disc swelling, without signs of posterior segment inflammation, treated with topical steroids every 2 hours, cyclopentolate 1% twice a day and oral acyclovir 200 mg five times a day, experienced rapid resolution of ocular signs and symptoms. His VA improved from 6/60 bilaterally to his baseline of 6/6 in the right eye and 6/5 in the left eye after three weeks of therapy [86]. However, since anterior uveitis can be self-limiting in 2 to 8 weeks, it can be difficult at times to ascertain the true impact of treatment on symptom resolution. Rennebohm [87] described six children with KD, five of whom developed anterior uveitis during the acute phase of KD. Both children treated with corticosteroids and cycloplegic drugs improved, as did the other three untreated children. Similarly, Puglise [75] described a 4-year-old child with KD who presented with bilateral swelling and hyperemia of the conjunctiva unresponsive to intense topical steroid therapy; however there was a reduction in conjunctival inflammation within one week of 30mg/kg of aspirin therapy and complete resolution in four weeks.

SMALL VESSEL VASCULITIS

ANCA-ASSOCIATED

Granulomatosis with Polyangiitis

This systemic necrotizing SVV is characterized by granulomatous inflammation of the upper and lower respiratory tract, with focal necrotizing glomerulonephritis. The disease shows a strong predominance for Caucasians, particularly those of northern European ancestry with a prevalence ranging from 23.7 cases per 1,000,000 people in France [88], to 63 cases per 1,000,000 people in the United Kingdom [89], and 95 cases per 1,000,000 people in Northern Norway [90]. It is slightly more common in men than in women with a 1.3 to 1.7:1 male to female ratio [62, 91], and typically occurs in the fourth and fifth decades of life [62, 88, 91]. The disease is rare in children, but when it occurs, it is four times more common in girls than boys [92]. The histopathology of GPA is characterized by a triad of multinucleated giant cell granulomatous inflammation, vasculitis, and necrosis [93].

The ACR [91] identified four diagnostic criteria for GPA, two of which must be present in order to make the diagnosis from among the following including, nasal or oral inflammation, an abnormal chest radiographic showing nodules, fixed infiltrates, or cavities, urinary sediment showing microhematuria or red cell casts, and granulomatous inflammation on biopsy. The presence of two or more criteria imparted a sensitivity of 88.2% and specificity of 92.0% for the diagnosis of GPA. Although serum ANCA level is not part of the ACR criteria, GPA is associated with ANCA, particularly c-ANCA, the presence of which had 99% specificity and 96% sensitivity for generalized GPA, and 67% sensitivity for the limited form [94]. Ocular findings are not part of the diagnostic criteria for GPA; however among patients with vasculitis [91], ocular inflammation, so noted as scleritis, episcleritis, and proptosis, had a sensitivity of 27.4% and a specificity of 96.9% for the diagnosis of GPA.

Ocular manifestations occur overall in 30% to 60% of patients with GPA [95-97], and are the presenting features in up to 16% of patients [97]. Ocular symptoms can be due to primary inflammation or focal vasculitis that affects the anterior and posterior segments of the eye causing conjunctivitis, episcleritis, and keratitis, and optic nerve vasculitis; or as a result of the contiguous spread of longstanding granulomatous sinusitis leading to proptosis, orbital pseudotumor and nasolacrimal duct obstruction. Vascular complications such as retinal artery occlusion can occur [98]. Frequent symptoms of orbital disease included ocular pain, epiphora and injection although proptosis, vision loss, diplopia and ophthalmoplegia [99, 100]. Rothschild and colleagues [62] noted ocular manifestations in 117 (34%) of 343 patients with GPA, exceeding the expected frequency of 11% for EGPA and 9% for MPA. Conjunctivitis was noted in 61 (51.2%) patients, followed by episcleritis in 46 (39.3%) patients, and orbital inflammatory disease in 23 (19.7%) patients. Other ocular manifestations also included blurred vision in 18 (15.4%) patients, uveitis in 9 (7.7%) patients, oculomotor nerve palsy in 5 (4.3%) patients, and sudden visual loss in 4 (3.4%) patients. Less common ocular manifestations were adnexal inflammation, scleritis, blepharitis, keratitis, optic neuropathy, retinal exudates and hemorrhages.

Hoffman and colleagues [96] noted ocular manifestations of GPA among 15% of 158 patients at presentation, and in 52% of those in the course of the illness. Conjunctivitis and dacrocystitis each occurred in 20% of patients; however, they were considered nonspecific features. Painful proptosis, often associated with visual loss due to optic nerve ischemia, and diplopia resulting from extraocular muscle entrapments, so noted in up to 2% of patients at onset of disease and in 15% throughout the course of illness, was a useful diagnostic feature typically caused by retro-orbital pseudotumor. Fauci and co-workers [97] identified proptosis in 15 of 49 (31%) patients with ocular involvement associated with GPA due to retro-orbital mass lesions.

Akikusa and co-workers [92] found eye involvement in 13 of 25 (52%) children with GPA at presentation and in 15 (60%) children over the course of their illness. Similar to adults, the commonest ocular manifestations were conjunctivitis in 14 (56%) patients, scleritis or episcleritis in 3 (12%) patients, and proptosis in 2 (8%) patients. Cabral and colleagues [101] reviewed the presenting clinical features of pediatric patients with GPA in three single-center cohorts and one multicenter cohort, noting ocular manifestations as common presenting features of GPA in children, with conjunctivitis occurring in up to 44% at presentation.

GPA is classified into classic and limited forms, the latter specifically excluding renal disease with a more favorable prognosis. Although both forms can have ocular manifestations of disease, Stavrou and colleagues [102] noted sight-threatening manifestations more often in 16 patients with classic GPA than 15 patients with limited GPA, further noting ocular manifestations in 13 (87%) limited GPA patients compared to 14 (89%) classic GPA patients. Moreover, 4 (27%) patients in the limited group experienced sight-threatening complications compared to 8 (50%) patients in the classical group.

Magnetic resonance imaging depicts mucosal inflammation and ulceration in the sinuses, nasal cavity and orbits in GPA with greater sensitivity than computed tomography (CT) and can aid in the determination of ocular involvement [103]. The serum ANCA test is useful in tracking patient responsiveness to systemic therapy. Shiuey and Foster [94] recognized that patients with GPA and non-normalizing serum ANCA levels after treatment often developed recurrent ocular despite apparent clinical remission. ANCA serology was further helpful in

determining disease severity and future complications in patients who present with episcleritis [104], moreover those with positive ANCA serology were more likely to have ocular complications including keratopathy, visual acuity (VA) less than 20/50, and vascular pannus.

Fauci and colleagues [97] recommended remission induction treatment of GPA with 2mg/kg/day of oral cyclophosphamide and 1mg/kg/day of prednisone, followed by tapering of prednisone to an alternate day administration, achieving complete remission rates of 93% for a mean duration of 48.2 months. Chan and colleagues [98] reported a patient with bilateral corneal ulcers and a VA reduced to 20/200 in the right eye and 20/70 in the left eye that was treated with 2 mg/kg/day of oral cyclophosphamide and 1mg/kg/d of prednisone. Two years later the VA in both eyes returned to 20/40, and the peripheral corneal ulcers healed although shallow peripheral corneal thinning remained. Foster and colleagues [105] studied a patient with GPA and progressive blurred vision, diplopia and increased supraorbital pressure, who was found to have a VA of 20/200 in the right eye, 20/40 in the left eye, 90% ophthalmoplegia in the left eye, and normal fundoscopic exam. The patient was treated with oral cyclophosphamide and prednisone, and one month later VA improved to 20/40 with complete resolution of ophthalmoplegia. Vischio and McCrary [106] who reported a 70-year-old man with left eye visual change, third nerve palsy and orbital mass compressing the optic nerve that was biopsied with proven GPA. The patient was treated with prednisone 40mg twice daily and cyclophosphamide 125mg daily, without visual improvement eleven weeks later. There is substantial ocular morbidity associated with GPA despite efficacious immunosuppressant therapy so noted in three enucleations among 140 patients [95]. Sadiq and colleagues [100] identified a subgroup of patients with GPA and orbital involvement with a poor prognosis evidenced by permanent visual loss in 43% of the patients.

Some patients with episcleritis, conjunctivitis, and anterior uveitis respond to topical therapy, but they should not be used because of secondary corneal thinning and perforation [107]. Although the surgical intervention is generally reserved for the performance of tissue biopsies, dacryocystorhinostomy was effective therapy for nasolacrimal duct obstruction, achieving symptomatic relief in 13 of 14 (93%) of patients [108].

Eosinophilic Granulomatosis with Polyangiitis

This systemic necrotizing small vessel vasculitis involves multiple organ systems, typically causing chronic rhinosinusitis, asthma, and eosinophilia. It is a rare disorder with an estimated annual incidence of 2.7 cases per 1,000,000 people and a period prevalence rate of 6.8 per million in those taking anti-asthma drugs [89, 109]. With most patients developing the disease in the fourth decade of life between age 14 and 74 years, EGPA has no gender predominance [62, 88, 110].

The ACR 1990 diagnostic criteria for EGPA [111] included six criteria, four of which were necessary from the following including, asthma, eosinophilia greater than 10%, neuropathy, pulmonary infiltrates, paranasal sinus abnormality, and extravascular eosinophils. The presence of four or more criteria yielded a sensitivity of 85% and a specificity of 99.7% for the diagnosis of EGPA. Although ANCA positivity is not part of the ACR's diagnostic criteria, it can be helpful in making the diagnosis in up to 70% of patients [88]. The characteristic changes of EGPA histopathology include necrotizing vasculitis and extra-

vascular necrotizing granulomas with eosinophilic infiltrates; however, early cases may be characterized by tissue infiltration by eosinophils without overt vasculitis [112].

Ocular features of EGPA can involve all parts of the eye and orbit. Takanashi and co-workers [113] classified the ocular manifestations into two types, pseudotumor or orbital inflammatory and ischemic vasculitis types. Patients with the pseudotumor type typically present with a chronically red eye, dacryoadenitis, myositis, periscleritis, perineuritis, conjunctival granuloma, episcleritis, orbital abnormalities on imaging, and ANCA seronegativity. Those with the ischemic vasculitis present with sudden visual loss, amaurosis fugax, anterior ischemic optic neuropathy, central retinal artery or branch retinal artery occlusion, normal orbital imaging, and ANCA seropositivity.

Among 270 patients with EGPA [62] 30 (11%) patients had ocular manifestations of which conjunctivitis was the most common so noted in 13 (43.3%) patients followed by blurred vision in 9 (30%) patients, oculomotor nerve palsy and sudden visual loss each in 4 (13.3%) patients. retinal vasculitis in 3 (12%) patients; orbital inflammatory disease, and retinal exudates each in 2 (6.7%) patients; and episcleritis, keratitis, uveitis, retinal thrombosis, and retinal exudates present each in 1 (3.3%) patient. Androudi and colleagues [114] described a patient with a 20 year history of severe steroid-dependent asthma, hematuria, pleuritis and sinusitis, who later developed uveitis and bilateral scleritis. Anterior ischemic optic neuropathy was reported by Lee and colleagues [115] in a 54- year-old man with bronchial asthma, allergic rhinitis, and sinusitis who presented with a sudden decrease in VA. Central retinal artery occlusion, another complication of EGPA, leading to sudden visual loss, was described among several other patients. Skrapari and colleagues [116] described a 50-year-old woman with left foot drop and painless visual loss in whom fundoscopy revealed central retinal artery occlusion. Kumano and co-workers [117] reported a 54-year-old woman with sudden loss of vision after tapering prednisolone from 30 mg to 10 mg per day, in whom central retinal artery occlusion was noted on FFA that showed delayed filling of the retinal and cilioretinal arteries, without leakage secondary to vasculitis. Hamann and Johansen [118] reported severe visual loss in association with central retinal artery occlusion evidenced by retinal whitening, macular cherry-red spot, combined with central retinal vein occlusion so noted by papilledema, retinal hemorrhages, and dilated and tortuous veins on Fundoscopy; fluorescein angiography revealed an absence of retinal filling.

Among 96 patients with EGPA described by Guillevin and colleagues [110] 3 (3.1%) patients presented with ophthalmic involvement. 2 had episcleritis, and 1 had bilateral exophthalmos. Koenig and co-workers [119] reported a patient with monocular blindness due to central retinal artery occlusion as the presenting feature of EGPA. McNab [120] described a 66-year-old woman with diplopia, foreign body sensation, redness and proptosis of the left eye, in whom orbital CT scan revealing increased density of the left orbital fat. In addition, Jordan and co-workers [121] reported two cases of EGPA who presented with dacryoadenitis and diffuse orbital inflammation. Takanashi and colleagues [113] recommended enhanced orbital imaging to look for inflammatory lesions. Fundoscopy is useful in identifying patients with central retinal artery occlusion.

The treatment of EGPA typically consists of corticosteroids and cyclophosphamide [122]; however plasma exchange can be added to treat patients with advanced renal disease, with expected survival rates approaching 90% [123]. There are no randomized, controlled studies of the efficacy of treatment on the ocular manifestations of EGPA. McNab [120] described a 66-year-old woman with orbital inflammation who responded rapidly and

completely to an oral prednisolone taper starting at 50 mg. A patient with anterior ischemic optic neuropathy responded to treatment with 24 mg of methylprednisolone daily however after one month, VA improved from 20/50 to 20/25 in addition to improved respiratory symptoms. Followup fundoscopy revealed subsiding papilledema and splinter hemorrhages but Goldmann perimetry showed residual central visual field defect [115]. Central retinal artery occlusion generally carries a less favorable prognosis.

Microscopic Polyangiitis

This necrotizing small vessel vasculitis typically affects the kidney causing a pauci-immune focal necrotizing crescentic glomerulonephritis, and the lungs causing pulmonary capillaritis. Its annual incidence is 3.6 cases per million people [124], with a mean age of onset over 50 years, and slightly male predominance with a male to female ratio varying from 1 to 1.2:1 [62, 125]. The histopathology of MPA is similar to GPA and EGPA in that there is a necrotizing vasculitis; however, the absence of granulomatous inflammation distinguishes MPA from GPA, as does absence of asthma and eosinophilia from EGPA [126].

In 1990 the ACR developed criteria for diagnosing the systemic vasculitides, but it did not distinguish MPA from PAN. However, the 2012 revised CHCC distinguished the two defining MPA as a necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels, often associated with necrotizing glomerulonephritis and pulmonary capillaritis; granulomatous inflammation is absent [3]. Although the presence of ANCA is not part of the diagnostic criteria, up to 65% of patients are positive for pANCA [125, 127].

Ocular findings are not part of the diagnostic criteria for MPA, and are much less common in MPA than in other AAV. Nevertheless, ocular involvement can occur in up to 24% of patients with MPA most often presenting as episcleritis or conjunctivitis [128]. A study by Rothschild and colleagues [62] in 280 patients with MPA found that 25 (9%) had ocular manifestations. Of those with ocular manifestations, the most common was conjunctivitis occurring in 7 (28%), episcleritis occurring in 5 (20%), and blurred vision occurring in 4 (16%). Other less frequent ocular manifestations included retinal vasculitis in 3 (12%), retinal exudates, optic neuropathy, sudden visual loss and oculomotor nerve palsy in 2 (8%) patients each, and scleritis, keratitis, uveitis, retinal hemorrhage in 1 patient (4%) each. Other studies report less frequent ocular manifestations of disease, so noted in a study by Guillevin and colleagues [125] in a study of 85 patients that found only 1 patient (1.2%) with ocular involvement.

Although ocular signs and symptoms are rarely presenting features of MPA, there are patients who initially present with ocular involvement. Hara and colleagues [127] described a patient who presented with hyperemia and photophobia of the eyes and found to have limbal infiltration, iritis and scleritis due to MPA. Altaie and co-workers [129] reported an 80-year-old woman with MPA who presented with painless vision loss in the right eye, and was found to have optic neuritis. Darlington and co-workers [130] described a 16-year-old woman with the initial presentation of peripheral keratitis.

Episcleritis and conjunctivitis are the commonest ocular manifestations of MPA, and it is critical to distinguish between the two since episcleritis generally implies a worse prognosis. Alrashidi and colleagues [131] demonstrated the importance of recognizing anterior scleritis

in the description of a patient with MPA with recurrent episodes of pain and redness for 7 years thought to be due to conjunctivitis. Eventually, the patient was diagnosed with episcleritis when she presented with severe ocular inflammation and vision loss, and slit lamp evaluation that demonstrated episcleritis. Thus, the authors suggest that a slit lamp evaluation should be done on patients with MPA to aid in the evaluation of the patient and determine appropriate treatment.

MPA is typically treated with corticosteroids and cyclophosphamide, and in severe cases plasmapheresis and IVIG have shown to be beneficial. If renal function is preserved, methotrexate may be added to induce remission. Maintenance therapy is recommended with azathioprine [132]. A favorable response to treatment occurs in up to 79% of patients with 5-year survival rates ranging from 65% to 80% [128, 133].

Since ocular features in MPA are rare, the effects of treatment on ocular disease have been documented through single patient reports or small series. Mihara and co-workers [134] described two patients, one of whom had hypopyon iridocyclitis in the right eye, and ophthalmoscopy with retinal cotton-wool spots in the left eye, both of which responded to oral prednisolone, topical instillation of 1% atropine sulfate and subconjunctival injections of betamethasone.

The patient with bilateral scleritis and corneal infiltration responded to the betamethasone treatment. Altaei and co-workers [129] described a patient with initial VA of hand movement only in the right eye that improved to 6/9 in the right eye after 4 months of pulsed 100 mg/day of methylprednisolone followed by 60 mg/day of oral prednisolone and 100 mg/day of azathioprine.

IMMUNE COMPLEX MEDIATED

Hypocomplementemia Urticarial Vasculitis

HUV is a rare severe systemic form of urticarial vasculitis characterized by chronic non-pruritic urticarial lesions, angioedema, ocular inflammation, arthritis or arthralgia, obstructive lung disease, and glomerulonephritis. Its exact incidence is unknown, but it is twice more common in women than in men, and its peak incidence is seen in the fifth decade of life [135]. The histopathology of HUV is characterized by an interstitial neutrophilic infiltrate of the dermis, and a necrotizing vasculitis with immunoglobulin or C3 deposits in the blood vessels on immunofluorescence [136].

The diagnostic criteria for HUV were first described by Schwartz and colleagues [137]. The major criteria are urticaria for more than 6 months duration and hypocomplementemia. The minor criteria, two of which are required for diagnosis, were dermal venulitis on biopsy, arthralgia or arthritis, uveitis or episcleritis, mild glomerulonephritis, recurrent abdominal pain, and a positive C1q precipitin test by immunodiffusion, with reduced circulating C1q levels. Exclusion criteria included significant cryoglobulinemia, elevated anti-DNA antibody titer, high titer of antinuclear antibody (ANA), hepatitis B virus (HBV) antigenemia, decreased C-esterase inhibitor levels, and inherited complement deficiency. HUV and SLE share many clinical features, thus it is important to note that COPD and uveitis are typically found in HUV, but not SLE [138].

Ocular manifestations of HUV are found in up to 60% of patients. A study by Wisnieski and colleagues [138] in 18 patients with HUV found that 11 (61%) patients had ocular manifestations, 8 (44%) had conjunctivitis, episcleritis, and/or inflammation of the uveal tract, while 3 (16.6%) had scleral inflammation and photophobia. Davis and colleagues [139] found that 21% of patients had episcleritis or uveitis, while none with normocomplementemic urticarial vasculitis had ocular manifestations. Iridocyclitis, so noted in two patients by Corwin and Baum [140] was postulated to result from immune complex deposits. Thorne and colleagues [141] described a 67-year-old-man with eye pain, redness, rash, arthralgia and malaise later noted to have bilateral anterior scleritis without evidence of keratitis or uveitis, and diagnosed with HUV. Mosawi and Hermi [142] described an 8-year-old boy with conjunctivitis who later developed episcleritis. The diagnosis of HUV is ultimately based on clinical presentation, laboratory findings, and tissue biopsy; however since ocular manifestations of disease are so pervasive, Wisnieski and co-workers [138] suggested that suspected patients should be screened for ocular inflammation with a slit lamp exam.

The treatment of HUV consists of dapsone and systemic corticosteroids, and nonsteroidal anti-inflammatory medication (NSAID) for symptomatic arthralgia and arthritis, and plasmapheresis in severe cases [135, 139]. Wisnieski and colleagues [138] studied 8 patients with C1q/HUV with conjunctivitis, episcleritis, and inflammation of the uveal tract, identifying three patients with scleral inflammation and noting that none developed chronic or irreversible ocular injury. All responded to prednisone and ophthalmic steroids. Thorne and colleagues [141] documented the response of scleritis to treatment in a 67 year-old-man with bilateral scleritis, who responded to 1 mg/kg/day of prednisone 1 mg/kg daily and 30 mg/kg/day of mycophenolate mofetil in six months. The response of iridocyclitis to cycloplegic and topical corticosteroids was shown by Corwin and Baum [140].

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis is a small vessel vasculitis involving the skin, joints, peripheral nervous system and kidneys. The disease is more common in Southern Europe than in Northern Europe or Northern America, and the prevalence of essential mixed cryoglobulinemia is reported to be approximately 1 case per 100,000 people [143]. The mean age of onset of CV is in the fifth to sixth decade of life, with an age at onset of 27 to 78 years, and a female to male ratio of 1.3 to 3:1 [144-146]. The histopathology of CV is characterized by a leukocytoclastic vasculitis, B-lymphocyte expansion and tissue B-cell infiltrates [146].

The 2012 Revised CHCC defined CV as a vasculitis with cryoglobulin immune deposits affecting small vessels associated with serum cryoglobulins. Skin, glomeruli, and peripheral nerves are often involved [3]. Ocular signs and symptoms are neither part of the diagnostic criteria for CV, nor are they very common.

The first ocular manifestation of CV was likely described by Wintrobe and Buell [147] in a patient suffering from multiple myeloma that had bilateral thrombosis of the central retinal veins and visual impairment. Other ocular manifestations included anterior uveitis, scleritis, and peripheral ulcerative keratitis. Ryan and colleagues [148] described a 42-year-old woman with CV who had attacks of acute arthritis and urticarial lesions with painful red eyes and photophobia, later found to have 4+ cellular infiltrates and flare on slit-lamp examination

consistent with anterior uveitis. Anterior uveitis was documented by Nicholson and Sobrin [149] in the description of a 40-year-old man with severe anterior uveitis associated with type II essential cryoglobulinemia. Scleritis and peripheral ulcerative keratitis were other manifestations so noted by Kedhar and co-workers [150] in a 49-year-old woman with necrotizing scleritis and peripheral ulcerative keratitis associated with Hepatitis C virus (HCV) infection.

Myers and colleagues [151] described in a 44-year-old man with chronic HCV-associated CV who developed sudden loss of vision in his left eye and abdominal pain. Fundoscopy revealed peripapillary cotton-wool spots and superficial retinal whitening in the macula. FFA revealed retinal vascular non-perfusion in the left macular and peripapillary region, but not in the periphery, consistent with Purtscher retinopathy. The authors proposed that the retinopathy developed as a result of complement-mediated microembolism leading to vaso-occlusion. Sauer and co-workers [152] documented a patient with Purtscher-like retinopathy associated with HCV-associated CV with complaints of visual loss. Purtscher retinopathy and hypertensive retinopathy were described by Gorevic and colleagues [153] among 22 patients with CV, 14 (63.6%) of whom had hypertension, and 8 (36.4%) with hypertensive retinopathy; the latter likely resulted from CV-mediated, renovascular hypertension.

Central serous chorioretinopathy is another ocular complication of CV. Cohen and colleagues [154] reported two patients with CV who presented with serous retinal and retinal pigment epithelial detachments resembling central serous chorioretinopathy. The authors postulated that the increased protein content of the choroid in patients with CV caused an abnormal excess of interstitial fluid to accumulate in the subretinal pigment epithelium or subretinal space resulting in retinal pigment epithelial detachment.

The treatment of CV consists of corticosteroids plus an alkylating agent which is associated with induction of remission in up to 62% of patients. Rituximab plus corticosteroids has more recently been found to be beneficial producing induction of remission in up to 64% of patients. Though the combination of rituximab and corticosteroids is the most effective treatment for CV, it is associated with infection in 42% [145] of patient so treated. In those with HCV-associated CV, treatment of HCV with pegylated IFN and ribavirin in addition to rituximab is the optimal treatment for most [155]. Nicholson and Sobrin [149] described a patient with CV who presented with severe anterior uveitis who did not respond to corticosteroids but improved with plasmapheresis and rituximab. Kedhar and co-workers [150] found that necrotizing scleritis and peripheral ulcerative keratitis due to CV improved with high-dose prednisone, pegylated interferon, ribavirin, and cyclophosphamide. Myers and colleagues [151] described successful treatment of Purtscher retinopathy with plasmapheresis, prednisone and cyclophosphamide leading to improvement in left eye VA from 1/200 to 20/200, and resolution of retinal whitening, cotton-wool spots and retinal hemorrhages observed on fundoscopy in six months.

Central serous chorioretinopathy, another ocular manifestation of CV, responded to treatment with laser photocoagulation so noted by Cohen and colleagues [154] in two patients who achieved near normal VA in both eyes.

IgA Vasculitis

This small vessel vasculitis is characterized by IgA IC deposition, in addition to nonthrombocytopenic palpable purpura, abdominal pain and arthritis. It is one of the most common vasculitides in children, with an annual incidence rate between 10-18 per 100,000 children per year [156, 157]. IgAV has a peak incidence in those under age 6, is slightly more common in males, and more frequent during winter months [156-158]. The pathology of IgAV is characterized by infiltration of small blood vessels with polymorphonuclear leukocytes, and the presence of leukocytoclasia [156].

The ACR diagnostic criteria have found that the presence of two or more of the following criteria were 89.4% diagnostically sensitive and 88.1% specific for IgAV including, age at onset before 20 years, palpable purpura, acute abdominal pain, and biopsy showing granulocytes around arterioles or venules [159].

Ocular manifestations of IgAV are rare, but case reports have documented a range of ophthalmologic complications. Recurrent episcleritis was one of the first ocular complications of IgAV in a 14-year-old girl who developed photophobia and intermittent ocular pain 5 weeks after the onset of joint symptoms [160], ophthalmologic evaluation of whom revealed episcleritis and engorgement of the episcleral vessels.

The association between anterior uveitis and IgAV was first reported by Yamabe and colleagues [161] in the description of a patient with nephritis, anterior uveitis and keratitis later. Muqit and co-workers [162] described a 42-year-old man with HSP complicated by keratitis and granulomatous anterior uveitis. Erer and co-workers [163] reported a 39-year-old man with IgAV who presented with three episodes of anterior uveitis, one of which was bilateral, and unilateral episodes of each eye. Kaur and colleagues [164] documented bilateral anterior uveitis associated with IgAV in an 11-year-old boy with a 4 year history of eye pain and photosensitivity. Uveitis in IgAV is thought to be due to circulating IC, which reach the eye and deposit in uveal tissues. IC can deposit in vascular endothelial cells, pigmented epithelial cells, and corneal endothelial cells, expressing adhesion molecules that allows leukocytes to migrate to the uveal tissue and cornea causing injury [165].

Although IgAV is not typically associated with frank bleeding, bilateral subperiosteal orbital hematomas are a recognized complication so noted by Ma'luf and colleagues [166] in a 5- year-old-boy who presented with bilateral exophthalmos and bilateral upper eyelid ecchymosis.

Wu and colleagues [167] reported a 6-year-old girl who developed sudden vision loss, and later found on fundoscopy to have a cherry red spot with severe retinal edema of the macula and peripallary area of the eyes, with disc edema and venous engorgement consistent with bilateral central retinal artery occlusion. Central retinal vein occlusion was reported in a 12-year-old boy with IgAV [168].

Other rare ocular manifestations include AION [169] and acute visual loss due to bilateral cystoid macular edema and cotton wool spots [170].

The treatment of IgAV varies with disease severity with milder cases responsive to supportive therapy and self-resolve in 6 to 16 weeks, and more severe involvement requiring systemic corticosteroids and IVIg [171]. Ocular manifestations of IgAV resolve with a combination of systemic and topical corticosteroids. A patient with episcleritis due to IgAV responded to corticosteroids, but had exacerbations of episcleritis whenever the alternate day

prednisone dose was tapered to less than 30 mg (160). Erer and co-workers [163] described a patient with anterior uveitis who had three recurrent episodes of anterior uveitis, each which resolved within days of treatment with topical corticosteroids. Kaur and colleagues [164] reported on an 11-year-old male with anterior uveitis that responded to systemic prednisolone, topical steroids and homatropine eye drops.

AION-associated IgAV responds moderately well to corticosteroid treatment as noted by Chuah and Meaney (169) in the care of a 54-year-old man with AION whose VA improved from counting fingers to 6/36 with 4 mg of daily prednisolone. Cystoid macular edema and cotton wool spots were noted to respond to 60 mg of oral prednisone with resolution of the macular edema in two days [170].

VARIABLE VESSEL VASCULITIS

Behçet Disease

This disorder is characterized by relapsing aphthous ulcers of the mouth, eye and genitalia [172]. The most widely used diagnostic criteria of BD were formulated by the International Study Group (ISG) [173] that include recurrent oral ulcerations plus any two of genital ulceration, typical defined eye lesions, typical skin lesions, or a positive pathergy. Recurrent oral ulcerations are categorized as minor aphthous, major aphthous, and herpetiform ulcerations that recurred at least three times in a 12-month period. Recurrent genital ulcerations are defined as aphthous ulceration and scarring. Eye lesions were defined as anterior uveitis, posterior uveitis or cells in the vitreous on slit lamp examination; and retinal vasculitis. Compatible skin lesions included erythema nodosum, pseudofolliculitis, papulopustular lesions, and acneiform nodules in post-adolescent patients not receiving corticosteroids. A positive pathergy test of cutaneous hypersensitivity was defined as positive when a sterile pustule developed after twenty four to forty-eight hours at the site of a needle prick to the skin [174]. Although the usual onset of BD is in the third or fourth decade of life, pediatric-onset cases have been described [175, 176]. Uluduz and colleagues [175] studied two large Istanbul BD cohorts totaling 728 patients, ascertaining and comparing pediatric-onset (26 patients) and adult adult-onset (702 patients)-neurological (NBD) that differed in male predominance and more frequent dural venous sinus thrombosis in pediatric patients compared to parenchymal neurological involvement in adults. Citirik and colleagues [176] described ocular findings in 34 pediatric patients that included panuveitis, posterior and anterior uveitis respectively in 53%, 32% and 15% of patients. Other ocular findings included cataracts in 59%, posterior synechiae in 24%, postoperative capsular opacification 24%, vitreous condensation after vitritis in 50%, optic atrophy in 30%, cystoid macular edema 15%, narrowed or occluded retinal vessels after retinal phlebitis and branched retinal occlusions in 6%, neovascularization of the disk and phthisis bulbi each in 3% of patients. Arai and colleagues [177] described the postmortem findings in a young man with BD with relapsing unilateral uveitis, sensorineural hearing loss, slight fever, and progressive CNS and autonomic nervous system involvement that included multifocal brainstem and cerebellar necrotic foci, perivascular neutrophilic inflammation, and perivasculitis.

Cortical venous sinus thrombosis (CVST) in BD most commonly presents with symptoms and signs of increased intracranial pressure with a rarity of venous infarcts. Prothrombosis when present, is presumed to commence as an endothelial disturbance. The treatment of BD-related CVST includes consideration of anticoagulation and corticosteroids alone or in association with another immunosuppressant agent.

Cogan Syndrome

Morgan and Baumgartner [178] described a 26-year-old man with recurrent pain, spasm and redness of the left eye with photophobia, excessive tearing, and marked conjunctival injection, followed by severe attack of dizziness, tinnitus, vertigo, nausea, vomiting, ringing in the ears, profuse perspiration, and deafness. A diagnosis of recurrent interstitial keratitis and explosive Menière disease was made however in retrospect this patient may have been the first reported case of CS associated with nonsyphilitic interstitial keratitis (IK). Vestibuloauditory symptoms were later described by Cogan [179]. Haynes and colleagues [180] set forth diagnostic criteria for typical CS according to the definitions established by Cogan [179] in a review of 30 patients seen at the National Eye Institute of the National Institutes of Health (NIH) by Cogan [179, 181] with symptoms of IK that developed abruptly and gradually resolved, associated with photophobia, lacrimation, and unilateral or bilateral eye pain. Such symptoms tended to recur periodically for years before becoming quiescent. Vestibuloauditory dysfunction was manifested by sudden onset of Menière-like attacks of nausea, vomiting, tinnitus, vertigo, and frequently progressive hearing loss that characteristically occurred before or after the onset of IK. However within one to six months of the onset of eye symptoms, auditory symptoms progressed to deafness over a period of one to three months, certainly no longer than two years.

Gluth [182] reviewed a cohort of CS seen at the Mayo Clinic between 1940 and 2002. The commonest symptoms at presentation were sudden hearing loss in 50%, balance disturbance in 40%, ocular irritation in 32%, photophobia in 23%, tinnitus in 13%, and blurred vision in 10%. Specifically noted inflammatory eye findings that occurred in the course of disease included interstitial keratitis in 77%, iritis or uveitis in 37%, oscillopsia in 25%, scleritis or episcleritis in 23%, and conjunctivitis in 10%.

Most patients with CS (58%) were treated with corticosteroids with an overall favorable response in both vestibuloauditory and ophthalmologic manifestations, with the remainder demonstrating only ophthalmologic (23%) or vestibuloauditory improvement (19%) alone (98). Other therapies included methotrexate, cyclophosphamide, azathioprine, entanercept, hydroxchloroquine, and IVIg therapy. Surgical cochlear implantation can lead to objective and subjective benefits with improved hearing recognition.

SINGLE ORGAN VASCULITIS

Primary CNS Vasculitis

Adult [183] and childhood isolated CNS angiitis [184], primary angiitis of the CNS [185], adult [186] and childhood PCNSV [187]; granulomatous angiitis of the brain (GAB)

(188) and granulomatous angiitis of the nervous system (GANS) [189], are equivalent terms for a prototypical primary vasculitic disorder restricted to the CNS of diverse cause and clinicopathologic expression.

The diagnosis of PACNS [185], like IACNS [183] relies upon the presence of the classic angiographic features of beading in cerebral angiographic studies or the histopathologic features of angiitis in brain and meningeal vessels in the absence of systemic vasculitis or another cause for the observed findings. Affected patients with PACNS present with headache of gradual onset accompanied by either focal neurological signs or diffuse cognitive changes, so noted respectively in those with involvement of either large named arteries or small meningeal and distal terminal cortical vessels. The clinical course can be rapidly progressive over days to weeks, or insidiously over weeks to months, with seemingly prolonged periods of stabilization.

Younger and colleagues [188] described symptoms and signs in four patients with GAB alone or in association with concomitant neurosarcoidosis, varicella zoster virus (VZV) infection, and Hodgkin lymphoma, and reviewed the clinical and laboratory findings in 74 additionally-proven cases. Mental change, headache, fever, focal weakness, and visual changes, were the commonest symptoms and signs at onset respectively in 58%, 54%, 21%, 15%, 9% at presentation, and in 78%, 54%, 21%, 42%, and 12% during the course of the illness. Visual symptoms included diplopia, amaurosis fugax, blurring of vision, and contiguous involvement of the eye in those with V1 dermatomal VZV lesions. Hemiparesis, quadriparesis, and lethargy were associated with a poor prognosis and mandated the need for combined meningeal and brain biopsy to establish the diagnosis followed by combination chemotherapy employing corticosteroids and cyclophosphamide.

Cupps and colleagues [183] noted neuro-ophthalmological involvement in two of four patients with IACNS. Patient 1 had transient hemifield visual loss accompanied by headaches before the angiographic diagnosis of IACNS with involvement of named cerebral vessels, followed several months later after commencement of combination immunosuppressant therapy by a one-week period of altered VA. Patient 3 had a unilateral fundus Roth spot, with markedly decreased VA and normal pupillary response before diagnostic cerebral angiography of IACNS showed narrowing of named cerebral vessels, followed months later after commencement of combination immunosuppressant therapy by occipital headaches, transient decreased visual acuity and a starburst image in the central visual field.

Figure 2. Branch retinal artery occlusion in a patient with isolated CNS vasculitis.

Calabrese and Mallek [185] reported eye signs in 15% of literature cases with angiographically or pathologically defined PACNS but in none of 8 Cleveland Clinic patients. Among 70 patients with angiographically-defined and 31 patients with pathologically-verified PCNSV described by Salvarani and colleagues [186], hemiparesis, unilateral numbness, blurred vision and decreased acuity were most common in those with angiographically-defined PCNSV, although persistent neurological deficit or stroke and headache were the commonest initial findings overall in 68% of patients. A granulomatous pattern of inflammation was seen most often in those with altered cognition and at an older age. Lanthier and coworkers [184], who described histologically-proven IACNS in two children, had one child (Case 2) with bilateral optic disk swelling and persistent conjugated gaze-evoked nystagmus at presentation. Among four children with angiographically-negative childhood PACNS described by Benseler and colleagues [187] one child (Patient 3) was noted to have gaze-evoked nystagmus. (Figure 2)

CONCLUSION

Ophthalmologic and neuro-ophthalmologic manifestations of primary systemic and isolated CNS vasculitis typically arise in association with ischemic vascular disease of the CNS. Although uncommon, such manifestations may be the first clue to underlying ischemic disease due to primary or secondary involvement of visual and eye movement pathways warranting further evaluation for CNS vasculitis.

ABSTRACT

There has been extraordinary research in the blood-brain barrier over the past decade. Once considered a static anatomical barrier to the traffic of molecules in and out of the central nervous system when fully developed in adults, and otherwise irrelevant to neuroscience and disease, the blood-brain barrier is now known not only to be fully functional in development, but vital in cerebrovascular angiogenesis. The cellular components and other molecular constituents of the blood-brain barrier, contained in a neurovascular unit, protect the central nervous system from injury and disease by limiting the passage of toxins, pathogens, and inflammatory effectors of the immune system. Blood-brain barrier breakdown has been recognized as an important factor in a variety of primary neurological diseases however such disturbances while common to primary and vasculitis of the central nervous system, has yet to be critically analyzed. The chapter provides a comprehensive review of the blood-brain barrier in health and disease, with special consideration to the pathogenesis of central nervous system vasculitis. This chapter reviews the history, neurodevelopment, ultrastructure, function, and clinicopathologic correlation and relevance to central nervous system vasculitis.

Keywords: blood-brain barrier, blood-nerve barrier, systemic vasculitis

INTRODUCTION

The past decade has witnessed an expansion of knowledge in the properties possessed by the blood-brain barrier (BBB) in health and disease as summarized in several excellent recent reviews [1-5]. In essence, the neurovascular unit of the BBB is comprised of capillary vascular and neural cells, extracellular matrix components, and a variety of immune cells that mediate local immunity. The schematized and electron microscopic (EM) appearance of cerebral capillaries in the BBB shown in Figures 1 and 2, demonstrate layers of pericytes adherent to the abluminal or parenchymal surface of endothelial cells, together surrounded by a layer of basal lamina comprised of extracellular matrix protein molecules. The end feet of neighboring astrocyte processes ensheath the blood vessels. Monolayers of adjacent endothelial cells that form tight junctions (TJ) strands shown in Figure 1, connecting adjacent endothelial cells by adhesions of transmembrane occludin, claudin, and junctional associated molecules [JAM] across the intercellular space while cytoplasmic scaffolding and regulatory proteins such as zona occludens type 1 and 2 [ZO-1, ZO-2] provide linkage to the actin cytoskeleton and initiate several signaling mechanisms via protein-protein interactions. Endothelia BBB cells are also linked by adherens junctions composed of vascular endothelial (VE)-cadherin, which mediates cell-cell adhesion interactions, linking adherens junctions to the actin cytoskeleton via catenins [2, 3]. Perivascular macrophages that reside between astrocyte endfeet and the vessel wall, mast cells associated with specific regions of the CNS; resident microglia that act as antigen presenting cells (APC), and circulating leukocytes that can penetrate the intact BBB via interactions with endothelial adhesion molecules (CAM) to mediate bidirectional crosstalk between immune cells and endothelium for normal surveillance, constitute the extended neurovascular unit (NVU) [2].

Breakdown or disruption of the BBB accompanies a variety of inflammatory and autoimmune, neoplastic, infectious, and neurodegenerative central nervous system (CNS) disorders, notably stroke, multiple sclerosis, brain trauma, human immune virus, infection,

and Alzheimer disease. These disorders are associated with the abnormal entry of plasma components, immune molecules and cellular elements that leads to further neural dysfunction and varying degrees of irreversible neural degeneration. Although there is little known about the role of BBB breakdown in primary and secondary CNS vasculitis, future progress could lead to improved understanding of primary and secondary forms of CNS vasculitis [6] with the prospect of even improving the outcome two potentially devastating disorders, childhood and adult primary angiitis of the CNS (PACNS) [7-9]. According to Weiss and colleagues [10] further understanding of the BBB could envision the use of new therapeutic strategies that bypass it, taking advantage of the selective expression of membrane bound proteins expressed by brain endothelia cells or circulating leukocytes to target new drugs, as well as improve the effectiveness of conventional systemic immunosuppression. This chapter reviews the history, neurodevelopment, ultrastructure, function, and clinicopathologic correlation and relevance to CNS vasculitis.

HISTORICAL BACKGROUND

In 1885, Ehrlich [11] provided the first suggestion of the presence of a barrier when a parenteral injection of vital dye into the bloodstream of mice penetrated practically every systemic organ except the brain turning them dark purplish-blue, leaving the brain and spinal cord pale white-yellow. Ehrlich himself thought that this difference was due to a low binding affinity. The existence of a barrier at the level of the cerebral vessels was postulated by Bield

and Kraus [12] and later by Goldman [13] and Lewandowsky [14] at the turn of the twentieth century, who jointly interpreted their experience in favor of a true BBB, later termed *Blut-Hirn-Schranke*. In 1967, Reese and Karnovsky [15] demonstrated a structural barrier to an intravenous injection of horseradish peroxidase (HRP) demonstrating exogenous peroxidase to the lumina of blood vessels and in some micropinocytotic vesicles within endothelial cells, but none beyond the vascular endothelium. The relatively scarce number of vesicles was a morphological feature of a functioning BBB. Their findings localized at a fine structural level a barrier composed of the plasma membrane and the cell body of endothelial cells and TJ between adjacent cells of the cerebral cortex. In 1969, EM studies by Brightman and Reese [16] in the mouse conclusively demonstrated endothelial and epithelial TJ that occluded the interspaces between blood and parenchyma or cerebral ventricles, constituting the ultrastructural basis for the blood-brain and blood-cerebrospinal fluid barriers. Feder [17] noted active exclusion of the small electron-dense tracer microperoxidase by intact TJ after parenteral injection supplementing the findings of Reese and Karnovsky [15]. Nagy and colleagues [18] examined fracture faces of cerebral endothelium in normal and hyperosmolar mannitol-treated rat brains to elucidate the organization of TJ in various segments of the cerebral vascular bed and the structural basis of BBB opening in hyperosmotic conditions. Their findings provided no direct evidence for the structural basis of BBB opening in hyperosmolar mannitol-treated rat brains noting extended TJ regions in capillaries and postcapillary venules. Shivers and coworkers [19] studied isolated rat brain capillaries employing freeze-fracture images of interendothelial ZO revealing complex arrays of intramembrane ridges and grooves characteristic of TJ. The ZO of these capillary endothelial cells were considered very tight.

NEURODEVELOPMENT

In contrast to the neuronal development, the vascular system undergoes blood vessel formation through the two distinct processes, vasculogenesis and angiogenesis. The former commences with endothelial differentiation from angioblasts to vascular plexuses, while the latter is associated with sprouting of new vessels from existing ones. Both vasculogenesis and angiogenesis are influenced by vascular endothelial growth factor (VEGF), a major attractive molecule for extending blood vessels especially endothelial tip cells [20], as well as by other molecules, blood flow and contact with surrounding tissues. Found at the growing end of extending vessels, the shaft of extending endothelial tip cells is composed of an endothelial cell chain made of stalk cells similar to the axon growth cone and its associated axonal shaft. *In vivo* imaging employing green fluorescent protein (GFP) depicts the advancing endothelial tip cell navigating the environment and sprouting from existing vasculature [21]

Several experimental observations have suggested the importance of the neurodevelopment of the BBB [5]. First, there are shared molecular and cellular mechanisms in both neurogenesis and angiogenesis [22, 23]. Four major families of axon guidance ligand-receptor pairs include Slit/Robo, semaphoring/plexin/neuropilin, Netrin/Unc5/DCC, and Ephrin/Eph, together mediating complex cellular navigational programs within axons as both chemoattractants and repellents, and directing the angiogenic tip cells toward its final destination.

Neuropilin-1 is necessary for endothelial tip cell guidance in the developing central nervous system [24]. Moreover, axonal terminal arborization parallels vessel sprouting. Similar to hypoxic tissue that secretes VEGF via hypoxia-inducible factor (HIF), a transcription factor that promotes cell survival through the downstream activation of numerous genes including *VEGF* [25]. Axonal terminals devoid of synaptic input secrete nerve growth factor (NGF), the expression of which is down-regulated when innervation occurs.

Second, there is co-regulation of these two systems in developing embryonic and adult brains [22, 26; 27]. Stubbs and colleagues [26] found that blood vessels provided a supporting niche in regions of adult neurogenesis. The investigators [26] employed Tbr2-GFP transgenic mice that served as a correlate for the expression of the intermediate progenitor cell (IPC) T-box transcription factor Tbr2, to examine the proximity of dividing cells in the subventricular (SVZ) and ventricular zone (VZ) of the shaking rat Kawasaki and reeler mutant mouse in relation to blood vessels throughout neurogenesis. Their findings which included the extension of neuritis toward and along labeled blood vessels supported the notion of vascular-neuronal interactions in development. Javaherian and coworkers [27], who likewise studied IPC in the SVZ of embryonic Swiss Webster mouse cortices, employed confocal microscopy to image the vast network of capillaries in the SV and SVZ. The authors [27] noted that Tbr2 cells divided near vascular branch-points suggesting endothelial tip cells contributed to the neurogenic niche for IPC, with ectopic overexpression of VEGF-A in a pattern that followed that of blood vessel development. These findings indicated that the developing cortical vasculature provided a microenvironment within the SVZ in which IPC accumulated and divided during neurogenesis.

Third, a structural and functional BBB complete with TJ appear as soon as cerebral vessels penetrate the CNS parenchyma [28, 29]. Johansson and colleagues [28] explained that the widely held view that the BBB was immature during development stemmed from teleological interpretations and experimental observations of high cerebrospinal fluid (CSF) protein levels in fetal CSF and the apparent passive passage of biomarkers during development. Instead, the blood-CSF barrier, like the BBB is functionally and morphologically mature from very early in development. The authors maintain that inconsistent terminology used in the literature such as leaky, immature, and developing, used to describe the barrier gives a connotation of TJ that are more permeable than their adult counterparts without evidence to support this concept. Mølgård and Saunders [30] noted well-formed complex TJ across cerebral endothelial cells in human embryos and fetuses by freeze fracture and thin section EM by 8 weeks of age, commensurate with the differentiation of brain capillaries. Efflux transporters are likewise expressed in cerebral endothelial and choroid plexus epithelial cells early in the fetal and postnatal rats [31]. Ballabh and colleagues [32] studied the expression and quantification of endothelial TJ molecules including claudin-5, occluding, and JAM by immunohistochemistry and Western blot analysis in blood vessels of germinal matrix, cortex, and white matter of fetuses and premature infants gestational age 16 to 40 weeks. The authors [32] noted no significant decrease in the expression of the endothelial TJ molecules claudin-5, occludin, and JAM-1 as a function of gestational age in germinal matrix compared with cortex and white matter suggesting that they were unlikely to be responsible for germinal matrix fragility and vulnerability to hemorrhage in premature infants. These findings are consistent with the concept that TJ molecules develop and perhaps mature early during human gestation. Ballabh and colleagues [33] observed that a paucity of

TJ or pericytes coupled with incomplete coverage of blood vessels by astrocyte end-feet, could instead account for the observed fragility of blood vessels in the germinal matrix of premature infants. Braun and colleagues [34] found that pericytes coverage and density that was less in the germinal matrix vasculature than in the cortex or white matter in human fetuses, premature infants, and premature rabbit pups. Although VEGF suppression significantly enhanced pericyte coverage in germinal matrix, it remained less than in other brain regions.

NEUROBIOLOGY AND CELLULAR INTERACTIONS

Endothelial Cell Interactions

The existence of the endothelial cell was first surmised by William Harvey, and first observed by Marcello Malpighi in blood capillaries using compound microscopy in the nineteenth century, and later by EM in the mid-twentieth century, revealing the presence of plasmalemmal vesicles or caveolae. The ability to culture EC later permitted even more detailed investigation of their activation and function *in vivo*. Derived from mesoderm via the differentiation of hemangioblasts and angioblasts, there are a few protein/mRNA marker candidates including platelet/endothelial cell adhesion molecule (PECAM)-1 in monocytes and VE-cadherin in fetal stem cells. Endothelial cells of the BBB not only provide a physical barrier between the systemic circulation and the brain, but assure the selective inward passage of ions, nutrients, and neuropeptides via specialized transport mechanisms. Sodium, potassium, chloride, hydrogen, bicarbonate and calcium ions are transported across the BBB via transporters located mainly along the luminal surface of endothelial cells including, the sodium and potassium adenosine triphosphate (ATP)- dependent transport pump, the sodium-potassium-chloride cotransporter (NKCC), sodium-proton, chloride-bicarbonate, and sodium calcium exchanges that assure optimal levels of brain electrolyte levels and intracellular pH. The transport of essential nutrients is assured by members of the soluble carriers (SLC) superfamily, located variably along the luminal and abluminal membrane including, glucose transporter-1 (GLUT1), monocarboxylic acid-1 (MCT-1); excitatory, organic acid (OAT), cation (OAC), amine and choline transporters (CTL1), respectively to transport lactate and ketone bodies as alternative energy neuronal sources, and sodium-independent or dependent removal of glutamate, aspartate, glutamine, histidine, and asparagine from the interstitial compartment of the brain. Other specific carrier-mediated transporters mediate the passage of transferrin, low-density lipoproteins, leptin, immunoglobulin G (IgG), insulin, and growth factors via receptor-mediated transcytosis via binding of the protein to specific receptors on the endothelial cell surface following by endocytosis of the ligand-receptor complex with passage across the cytoplasm and exocytosis at the opposite side of the cell [35] and via the formation of caveolae or vesicle formation for the transport of macromolecules [36]. Transmigration of cellular elements across endothelial cells of the BBB during inflammation including leukocytes, neoplastic cells, and pathogenic viruses, bacteria and yeasts, investigated in experimental animal models utilizing HRP, highlighted the role of caveolae as mini-transporters of the CNS [36]. Unique systems of modified caveolae that fuse together forming transendothelial cell channels and later vesiculo-canalicular or vesiculo-tubular

structures (VTS) or vesiculo-vacuolar organelles (VVO), appear to be an important gateway to the CNS in damaged endothelial cell populations [36]. Transportation of potentially toxic endogenous or xenobiotic lipid-soluble nonpolar molecules from the brain to the blood are accomplished by transporters located along the luminal membrane such as the ATP binding cassette (ABC) transporter P-glycoprotein 1 (P-gp or Pgp) (multidrug resistance protein 1 [MDR1] or ATP-binding cassette sub-family B member 1 [ABCB1]) respectively important in the distribution of CNS tumor drug therapy [37] and the active efflux of the anti-human immunodeficiency virus type 1 (HIV1) nucleoside drug abacavir at the BBB [38-40]; and breast-cancer resistance protein (BCRP) and multidrug resistance related protein (MRP) 1, 2, 4 and 5 efflux transporter pumps that serve as defense mechanisms and determinate bioavailability and concentration of many CNS drugs important in the treatment of CNS cancers [41] such as the novel tyrosine kinase inhibitor dasatinib [42], and the efflux transportation of the protease inhibitor lopinavir that contributes to its poor oral bioavailability in the treatment of HIV1 [43]. The neuroinflammation and progression of damage associated with focal cerebral ischemia appears to be modulated by upregulation of other MRP protein molecules that activate Toll-like receptor (TLR) signaling contributing to neuroinflammation and progression of ischemic cerebral damage [44].

Transendothelial migration of circulating leukocytes involves a multistep process. Leukocyte adhesion molecules (LAM) expressed on the surface of EC initiate binding of leukocytes as a beginning step in the in their entry in brain tissue which later includes rolling adhesion to EC, firm adhesion, and transmigration. Although less well understood, the molecular mechanism is believed to involve endothelial CAM including CD99, platelet ECAM (PECAM-1)/CD31, vascular CAM-1 (VCAM-1) (important in firm adhesion); junctional adhesion molecule-1; expression of leukocyte adhesion molecules E- and P-selectin (rolling adhesion); cytokine responsiveness so noted *in situ* and in cell culture [45, 46] and expression of the integrins alpha4- and beta-2. Inflamed capillary endothelia support transmigration of different subsets of leukocytes. There are two routes for leukocytes to pass through endothelial cell, the so called paracellular route, or through the endothelial cell itself or transcellular route. The BBB with its abundance of TJ complexes relies primarily on the transcellular route as it does for solute and fluid transport. Neutrophil recruitment is partially dependent ICAM-1, and expresses L-selectin and lymphocyte function-associated antigen (LFA)-1 but not chemokine C motif receptor 7 (CCR7), which may explain why granulocytes roll but do not arrest for transmigrate in high endothelial venules (HEV).

Pericyte Interactions

Brain endothelial cells are exposed to a myriad of pericyte interactions [47] in the regulation of brain angiogenesis, endothelial cell TJ formation, as well as the differentiation, microvascular vasodynamic capacity, structural stability, and neuroimmunologic network operations of the intact BBB [48]. Rouget [49] first ascribed capillary contractility to pericytes but Zimmermann [50] named the cell and described its morphologic aspects. The presence of smooth muscle cells in association with pericytes and the absence of a smooth muscle layer from capillaries and postcapillary venues influenced early views ascribing contractile properties to narrow capillaries hence regulate microvascular flow even though a

number of subsequent experimental studies failed to substantiate it [51, 52]. Smooth muscle actin was conclusively demonstrated in pericytes by immunocytochemistry employing smooth muscle α -actin isoform specific antibodies and immunogold labelling in conjunction with EM noting that smooth muscle α -actin expression in capillaries was limited exclusively to pericytes and not present in endothelial cells [53]. Since the histochemical localization of smooth muscle α -actin is demonstrated in precapillaries and not in midcapillaries, it has been suggested that smooth muscle α -actin containing capillaries are involved in contractility and the control of capillary blood flow in the BBB [54].

Unlike other perivascular cells, they lie within the microvessel basal lamina and contribute to its formation. Typical CNS pericytes are flattened or elongated, stellate-shaped solitary cell with multiple cytoplasmic processes encircling the capillary endothelium and contacting a large abluminal vessel area. Brain pericytes are characterized by granular deposits present in lysosomes that strongly react with acid phosphatase, a finding that led to consideration of a phagocytic role [55]. They rapidly phagocytose an intravenous injection of HRP which can be employed as a pericytes histochemical stain. The number of granular lysosomes in brain pericytes increases with disruption of the BBB. Several other markers have been employed in the identification of pericytes including, smooth muscle α -actin (SMA), desmin, polydendrocytes (NG2 cells), platelet-derived growth factor receptor (PDGFR)- β , aminopeptidase A and N, regulator of G-protein signaling 5 (RGS5) and the promoter trap transgene *XlacZ4* [56].

An active role of pericytes in the BBB was inferred from the localization of γ -glutamyl transpeptidase (GGTP) in brain capillary endothelial cells and pericytes, both *in vivo* and *in vitro* [57]. This heterodimeric glycoprotein distributed on the external surface of the cell catalyzes the transfer of γ -glutamyl from glutathione to accept peptides and functionally appears to be concerned with transport of large neutral amino acids across the BBB. Detectable amounts of GGTP are found in other regions of the brain with an intact BBB but not in those that lack one such as the median eminence. Abnormal platelet derived growth factor (PDGF)-B and PDGF- β signaling plays a critical role in the recruitment of pericytes to newly formed vessels, and when deficient, as in knockout of *pdgfb* and *pdbfrb*, leads to perinatal death due to vascular dysfunction with associated vascular leakage and hemorrhage.

Pericyte-endothelial cell signaling factors have been identified. Sphingosine-1-phosphate (SIP) signaling triggers cytoskeletal, adhesive, and junctional changes, affecting cell migration, proliferation, and survival [58]. Angiopoietin-Tie2 signaling in the vascular wall involved in reciprocal communication between endothelial cell and pericytes, such as may be seen in *ang1*- or *tie2*-null mice deficient in Ang1, leads to defective angiogenesis and poorly organized BM, with reduced coverage and detachment of pericytes. Conversely, overexpression of Ang1 leads to expanded and stabilized, leakage resistant microvasculature [59, 60].

The importance of CNS pericytes has been underscored by their proposed role in neuroimmunological networks associated with BBB function. First, CNS pericytes may be actively involved in the regulation of leukocyte transmigration, antigen presentation, and T-cell activation. They constitutively express low levels of VCAM-1 and ICAM-1, which have costimulatory activity in main histocompatibility cell (MHC)-class II dependent antigen presentation; leukocytes cluster on pericytes in culture [48] suggesting a role in inflammation. Smooth muscle pericytes present antigen *in vivo* and differentially activate Th1 and Th2

CD4-T cells. Moreover, CNS pericytes produce a number of immunoregulatory cytokines including interleukin (IL) 1 β , IL-6, and granulocyte-macrophage colony stimulatory factor (GM-CSF) [61]. Transforming growth factor (TGF)- β produced in an active form in pericytes/endothelial cocultures, may function as an endogenous immunoregulator at the BBB [62]. It is therefore of interest that TGF- β 1 inhibits cytokine-induced CNS endothelial cell activation in isolated rat CNS microvessels [63]. To further emphasize the importance of pericyte interactions in association with endothelial cells, there are no known genetic human diseases due to pericyte deficiency.

Astrocyte Interactions

The intimate relationship of astrocytes and blood vessels was appreciated by Cajal [64] and Golgi [65] in the late nineteenth century. Since then, ultrastructural studies have shown that astrocytic endfeet in the perivascular astroglial sheath leads to a complete covering of brain microvessels [66]. Signaling at the gliovascular interface is facilitated by astrocyte-specific proteins and channels in astrocyte endfeet including, aquaporin-4, connexin 43, purinergic receptors, and potassium channels [67]. Moreover, ultrastructural studies have demonstrated that processes of vasoactive neurons for the regulation of cerebrovascular tone, in particular those expressing noradrenaline, synapse onto astrocytes rather than directly onto blood vessels [68]. Altogether, these findings support the observation that astrocytes one of the more numerous cells in the CNS, are important determinants of the intact BBB and crucial as well for ionic homeostasis, neurotransmitter uptake, synapse formation, and neurodevelopment. Zhang and Barres [69] have reviewed the differences in astrocyte morphology, developmental origin, gene expression profile, physiological properties, function and response to injury and disease. Two essential roles of astrocytes, in neurovascular coupling and the regulation of lymphocyte trafficking across the BBB have been extensively studied.

All signaling molecules targeted to the cerebral vasculature must first act on, or pass through astrocytes in order to reach smooth muscle cells in the vessel wall. It is now recognized that neurotransmitter-mediated signaling has a key role in regulating cerebral blood flow, and that much of this control is mediated by astrocytes [70]. Moreover, cerebral blood flow may be controlled by capillaries as well as by arterioles. The glial and neuronal control of cerebral blood flow has been studied in brain slices [71]. Koehler and colleagues [72] demonstrated that electrical field stimulations in brain slices led to an increase in intracellular calcium in astrocyte cell bodies, which when transmitted to perivascular endfeet, was followed by a decrease in vascular smooth muscle calcium oscillations and arteriolar dilation.

The increase in astrocyte calcium after neuronal activation was in part mediated by activation of metabotropic glutamate receptors. Calcium signaling *in vitro* was influenced by adenosine acting on A2B receptors and by epoxyeicosatrienoic acids (EET) shown to be synthesized in astrocytes. Moreover, prostaglandins, EET, arachidonic acid, and potassium ions are candidate mediators of communication between astrocyte endfeet and vascular smooth muscle. Astrocytes appear to be capable of transmitting signals to pial arterioles on the brain surface to ensure adequate blood flow to feeding arterioles. Therefore these cells

play an important role in the coupling of dynamic changes in cerebral blood flow in association with neuronal activity.

Koehler and colleagues [72] provided insight into the morphological aspects of neurovascular coupling at the capillary level of the BBB. At least one astrocyte endfoot process contacts a blood vessel and those abutting capillaries and larger vessels express connexin-43 and purinergic P2Y receptors, which together permit Ca^{2+} increases to be transmitted 60 μm or more along the abluminal side of the vessel wall. Astrocytic cells are therefore in a unique position for sensing neuronal activity, integrating that information, and communicating with blood vessels in brain parenchyma. While neurons do not directly innervate intraparenchymal vascular smooth muscle, subpopulations of GABAergic interneurons come into close contact with astrocyte foot processes and elicit vasodilation. Such neurons might modulate vascular function through stimulation of nitric oxide (NO) synthase (NOS) activity, release of vasoactive peptides, or an astrocyte signaling mechanism.

Hudson and coworkers [73] studied trafficking of peripheral blood mononuclear cells (PBMC) across feline brain endothelial cells (FBEC) in cell culture system after the addition of combinations of different configurations of astrocytes and microglia in a model of feline immunodeficiency virus.

The addition of astrocytes to FBEC significantly increased the adherence of PBMC which was suppressed by the addition of microglia, whereas the latter alone had no effect on PBMC adherence. Whereas all PBMC showed some level of trafficking across FBEC, monocytes and B cells were significantly increased if astrocytes were present. The exposure of astrocytes notably increased the percentage of trafficking CD8 T-cells from 24% to 64%, while microglia led to a significant reversal in the preferential trafficking of CD8 cells in the presence of astrocytes. Astrocytes are capable of secreting various cytokines and chemokines in the upregulation of adhesion molecules and T-cell ligands in intact endothelial cells such as ICAM, VCAM, E-selectin, and PECAM. Human cocultured human endothelial cells and astrocytes increase the expression of ICAM-1 due to inflammatory activation by hypoxia *in vitro* [74].

Other studies have demonstrated that astrocytes are a source of IL-6, TNF- α , and MCP-1 which contribute to the CNS inflammatory response [75]. Trafficking of PBMC along the endothelial cell of the BBB is a complex mechanism that involves major subsets of immune cells and relies heavily on astrocyte, microglia and endothelial cell interactions, moreover, astrocytes appear to be an active factor in the recruitment of immune cells, while microglia appear to curtail this activity.

IMPLICATIONS FOR CEREBRAL VASCULITIS

There is an extensive literature of BBB biology in health and in widely differing neurological disorders including stroke [76], epilepsy [77], multiple sclerosis [78], Alzheimer disease [79], motor neuron disease [80], Parkinson disease [81], trauma [82], glioblastoma [83], HIV encephalitis [84] and systemic lupus erythematosus (SLE) [85]. Between 40 and 70% of patients with SLE have involvement of the central nervous system (CNS) [86], yet unlike systemic and primary CNS vasculitides, the role of the BBB in CNS lupus has been the subject of intense study employing animal models and human clinical data.

The BBB is crucial because it maintains the brain internal milieu constant, allowing optimal neuronal function. Loss of BBB integrity leads to influx of inflammatory cells, and molecules such as autoantibodies causing brain injury. Earlier studies using the well-established MRL/*lpr* mouse model that reflects the events that occur in human CNS lupus, revealed loss of BBB integrity with worsening disease [87, 88] due to chronic activation of the complement cascade with the generation of the anaphylatoxins, C3a and C5a, and aggravated C5a/C5aR signaling. In cell culture, C5a causes neuronal cells to become apoptotic, and binds to two receptors, the G-coupled, C5aR1 and the alternate receptor, C5aR2 [89]. C5a/C5aR1 signaling mediates a number of biological processes, including chemotaxis and degranulation of mast cells, basophils, neutrophils and eosinophils. It increases vascular permeability, generation of reactive oxygen species, and enhances production of cytokines from monocytes and macrophages. Whether C5a/C5aR signaling is protective or neurotoxic depends upon the setting with increases in circulating C5a leading to poor outcomes in CNS lupus [89].

Hopkins and colleagues [90] measured levels of complement anaphylatoxin split products, C3a and C5a, in the circulation of patients with SLE who were followed serially. Means complement levels were significantly higher during periods of lupus flare compared to those during a stable period, with the highest levels seen in patients with CNS involvement. Pathologic specimens from two cases who died during an acute lupus flare revealed neutrophils occluding the cerebral and systemic intestinal vessels.

C5a also contributes to cellular apoptosis in lupus [91] wherein treatment with the C5aRant, inhibiting C5a/C5aR signaling results in significant and substantial decreases in brain pathology in MRL/*lpr* mice, leaving upstream potentially protective complement activation events intact. There was evidence for a relationship between complement activation, inflammation and neuronal viability in lupus brain tissue. C5aR1 is present predominantly on blood myeloid cells, but is also constitutively expressed on several brain cell types including endothelial cells, which contribute to BBB integrity. Such studies shows the possible neuroprotective role for C5aR antagonists in MRL/*lpr* mice, and indicates a potential future avenues of research for systemic and primary CNS vasculitides.

CONCLUSION

There has been extraordinary research in the blood-brain barrier over the past decade. Once considered a static anatomical barrier to the traffic of molecules in and out of the CNS, the BBB of children and adults is now recognized to be fully functional and vital to both cerebrovascular angiogenesis and normal homeostatic maintenance. The cellular components and other molecular constituents of the blood-brain barrier, contained in the NVU protect the CNS from injury and disease by limiting the passage of toxins, pathogens, and inflammatory effectors of the immune system. The implications of BBB disruption in cerebral vasculitis have yet to be appreciated, however comparisons to CNS lupus may lead to a better understanding of the neural mechanisms involved in disease pathogenesis and BBB integrity, and efficacious neuroprotective treatment strategies.

INTRODUCTION

Vasculitis is a term used to describe a diverse spectrum of diseases characterized by inflammation of the blood vessels that may progress to ischemic injury of the central nervous system (CNS) resulting in a myriad of focal and generalized neurologic symptoms. The injury is usually secondary to mural changes resulting in vessel stenosis or occlusion. Endothelial inflammation promotes intraluminal coagulation and thrombosis [1]. Perivascular inflammatory changes and edema contribute to the pathologic picture. Arterial and venous components may be involved separately or together and dural sinuses may be affected. Generalized inflammatory processes may produce a secondary encephalitis or myelitis. Although the CNS vasculitides can have a wide range of clinical, radiographic and pathologic manifestations, they also resemble more common non-inflammatory and occlusive vascular and connective tissue diseases. The radiological aspects of CNS vasculitis have evolved in the past decade [2]. No one single imaging modality is sufficient or preeminent. A combination of studies is typically required for a confident diagnosis of CNS vasculitis.

OVERVIEW AND CLASSIFICATION

With an estimated worldwide incidence of 20 per million for eosinophilic granulomatosis with polyangiitis (EGPA) also known as Churg-Strauss syndrome, 10 per million for granulomatosis with polyangiitis (GPA), 2.6 per million for Takayasu arteritis (TAK), and 0.9 per million for polyarteritis nodosa (PAN) [3, 4], and only a fraction of patients presenting with CNS involvement, it is important for clinicians to be familiar with clinical and neuroradiologic presentation of vasculitis. This is especially important in young and middle aged adults where the prevalence of atherosclerotic disease is low [5, 6].

The historical aspects of the classification of the vasculitides are reviewed elsewhere [7, 8]. Early classification schemes were based upon pathological parameters such as large, medium, or small vessels size; location of the vessel such as the aortic arch, pulmonary, abdominal, or skin; caliber of vessels including muscular artery, arteriole, venule, vein or combination thereof; histopathological characteristic of the inflammatory cell infiltrate whether polymorphonuclear, mononuclear, eosinophilic, giant cell or epithelioid cell types; location of the vascular inflammation such as intimal, media, elastic lamina, adventitial, or panarteritis; and the presence of immune complexes.

Cupps and Fauci [9] summarized the advances of the preceding decades recognizing several clinicopathologic categories for the vasculitides. The PAN group of systemic necrotizing vasculitis comprised classic PAN and the small vessel vasculitis EGPA. Hypersensitivity vasculitis comprised serum sickness, Henoch-Schönlein purpura, now termed IgA vasculitis (IgAV), and cryoglobulinemic vasculitis. GPA was separated from PAN and EGPA. The giant cell arteritis (GCA) category comprised temporal arteritis, now termed GCA, and TAK, recognized more for the unique location of vasculitic involvement and inflammatory giant cell composition.

To illustrate the clinical importance placed on the angiographic manifestations of the PAN group of primary systemic vasculitides, Citron and colleagues [10] described multi-organ arteritis including the CNS in a highly publicized report of fourteen Los Angeles multidrug abusers. The drug closest to a common denominator was intravenous use of methamphetamine by all but two patients and exclusively by one. Acute vessel lesions of fibrinoid necrosis of the media and intima with infiltration by polymorphonuclear cells, eosinophils, lymphocytes and histiocytes, followed by vascular elastic and vascular smooth muscle destruction resulting in lesions considered typical for PAN. However substantiation of necrotizing arteritis was present in only four of the fourteen patients. Citron and Peters [11] responded to the criticism from Baden [12] that he had not observed a causal relation between drug abuse and necrotizing arteritis at the Office of Chief Medical Examiner of New York City for the past one-half century among thousands of autopsied drug abusers, with the countering opinion that evidence of aneurysms, noted in thirteen of the fourteen patients, was ample proof of arteritis.

The contribution of angiography to CNS vasculitis commenced with the identification of angiographic beading and a sausage-like appearance of cerebral vessels at sites of presumed arteritis, first described in GCA by Hinck and coworkers [13] in 1964. Cupps and Fauci [14] established the utility of cerebral angiography in the diagnosis of histologically-proven isolated angiitis of the CNS or primary angiitis of the CNS (PACNS) in 1983. As giant cells

and epithelioid cells, usually found at postmortem examination in such patients were an inconsistent finding in a meningeal and brain biopsy and therefore considered unnecessary for antemortem diagnosis, Moore and colleagues [15] considered angiography necessary for diagnosis noting that normal cerebral angiograms had shown postmortem evidence of CNS vasculitis affecting only small vessels. This prevailing opinion was shared by Calabrese and Mallek [16] who proposed criteria for the diagnosis of primary angiitis of the central nervous system (PACNS), and Hajj-Ali and Calabrese who later separated PACNS from the reversible cerebral vasoconstrictive syndrome (RCVS), characterized instead by transient nonvasculitic narrowing of intracranial vessels [17].

By 1990, Hunder and colleagues [18] on behalf of the American College of Rheumatology (ACR) noted that the goal in classification was to identify sets of sensitive criteria that recognized a high proportion of patients with a particular form of vasculitis, while specifically excluding a high proportion of those with other diseases. Although highly specific and sensitive classification criteria might prove useful in the depiction of patients for epidemiologic studies and therapeutic trials, such criteria might not necessarily include the full spectrum of manifestations of a particular vasculitic disease, which was instead the role of formal diagnostic criteria. Lie [19] noted that while a definitive diagnosis of vasculitis almost invariably required histological documentation, the interpretation of a diagnostic tissue sample was subject to variables as diverse as the pathologist's experience, tissue selection, sample size, chronological age of the disease, and any prior treatment at the time of the biopsy. The angiographic appearance of aneurysms or occlusions of visceral arteries not due to arteriosclerosis, fibromuscular dysplasia or other non-inflammatory causes, were useful in the classification of PAN [20] with a sensitivity of 73.5% and specificity of 89.2%. The angiographic features of narrowing, aneurysm, or occlusion of the aorta or its primary branches, were employed in the classification of TAK [21] with sensitivities and specificities of 85.5% and 81.2%, 20.3% and 95.9%, and 51.6% and 86.1%, respectively. In the same 1990 volume of the journal, *Arthritis and Rheumatism*, the ACR Subcommittee on Classification of Vasculitis noted no diagnostic features of angiography useful in the classification criteria of EGPA [22], GPA [23], hypersensitivity vasculitis [24], IgAV [25], or GCA [26].

Jennette and colleagues [27, 28] held two Chapel Hill Consensus Conferences (CHCC) beginning in 1994 [27] and again in 2012 [28], establishing the nomenclature or nosology of systemic vasculitides. However, different from the ACR Subcommittee on Classification of Vasculitis [18], Jennette and colleagues [27, 28] incorporated prevailing knowledge about etiology, pathogenesis, pathology, demographics, and clinical manifestations, and employed a model of the predominant caliber of involved vessel that delineated the three major categories of systemic vasculitis including large size vessel vasculitis (LVV), medium size vessel vasculitis (MVV), and small sized vessel vasculitis (SVV) types, adding further distinctions as to the structural and functional characteristics of particular vascular beds, as well as the known biochemical and functional properties that rendered them susceptible to vasculitic injury. With about twenty-six recognized vasculitides in the 2012 revised CHCC, many of which demonstrate overlap in affected involved arteries, coupled with advances in the neuroradiologic techniques for discerning CNS involvement, there has been heightened interest in imaging the cerebral vasculature.

Küker [29] differentiated the entities of extracranial LVV, and intracranial MVV and SVV noting that vasculitic involvement of the internal carotid (ICA), common carotid (CCA),

M1 and A1 segments of the middle (MCA) and anterior cerebral arteries (ACA), intracranial vertebral and basilar arteries, and P1 segment of the posterior cerebral artery (PCA), generally regarded as intracranial LVV, would instead be considered systemic MVV by 2012 Revised CHCC nomenclature [28].

Moreover, vasculitic involvement along arterial vessels distal to the MCA bifurcation as well as communicating vessels such as the anterior (AComm) and posterior communicating (PComm) arteries, were still considered MVV systemically although intracranial. They may not be demonstrable along with intracranial LVV by magnetic resonance imaging (MRI), magnetic resonance angiography (MRA) or computed tomographic angiography (CTA), and may require conventional angiography (CA) for luminal irregularity to be visualized.

The smallest muscular arteries and arterioles within the brain parenchyma, as well as, the capillaries and proximal venules, all considered intracranial SVV by their lumen size corresponding to a caliber of 200 to 500 microns or less [30, 31], and considered beneath the resolution of invasive and non-invasive neuroimaging, require tissue biopsy to diagnose vasculitic involvement. The radiologic findings of CNS vasculitis may be similar to nonvasculitic inflammatory vasculopathies such as systemic lupus erythematosus (SLE), and other non-inflammatory vasculopathies such as atherosclerosis and spontaneous dissection in association with connective tissue disease and infection.

Examples of the neuroradiographic imaging of systemic LVV due to TAK and GCA (Figures 1-3), MVV in association with PAN (Figure 4), SVV related to EGPA (Figure 5), SLE (Figure 6), Behçet disease (BD) (Figure 7), PACNS (Figures 8-11), human immunodeficiency virus (HIV) (Figure 12), and RCVS (Figure 13) are all shown at the end of the chapter.

NEURORADIOLOGIC APPROACH TO CNS VASCULITIS

Küker [29] described three steps in the diagnostic evaluation of CNS vasculitis beginning with the demonstration of brain lesions by T₂- and diffusion and perfusion-weighted MRI, followed by the delineation of underlying vascular pathology by 1.5 Tesla (T) MRA to study the entire course of the carotid and vertebral arteries, as well as the circle of Willis. Time-of-flight (TOF) MRA sequences permits detection of more subtle stenoses and improves spatial resolution, as well as mural thickness in basal brain arteries with MRA source images; moreover, MRI may discern mural enhancement. Conventional angiography with digital subtraction (DSA) is employed to evaluate medium-sized and small-sized brain vessels, the status of cerebral hemodynamics, and assess brain perfusion.

Gomes [32] divided available neuroimaging studies into three groups including those that investigated the brain parenchyma, vessel lumen and vessel wall. Parenchymal findings, while least specific, were necessary to detect the presence of disease as well as to follow progression and remission status. Vessel lumen abnormalities, while highly suggestive for systemic vasculitis when present, were considered nonspecific and insensitive in the diagnosis of intracranial SVV.

Parenchymal Imaging

The MRI findings of CNS vasculitis have been previously described [33-36], the commonest of which are T₂/fluid attenuation inversion recovery (FLAIR) hyperintense lesions secondary to ischemia distributed throughout subcortical and deep white matter, the deep grey nuclei and the cortices. The MCA territory was the commonest involved in CNS vasculitis [37, 38]. Diffusion weighted imaging (DWI) helps to distinguish acute, subacute and chronic ischemia and is thus mandatory. Lesions are frequently bilateral and of differing ages. Involvement of multiple vascular territories or lesions within a frankly non-vascular territorial distribution may be clues to the diagnosis of CNS vasculitis although they can also be seen in association with thrombophilic and cardiogenic multiple embolic process that produce ischemia. Ischemic lesions were present in up to one-half of patients with PACNS [35]. Nonspecific white matter changes, which may be the only finding in symptomatic patients [39, 40], would be unlikely findings of atherosclerotic hypertensive disease in young patients, yet sometimes difficult to distinguish from CNS demyelinating disease.

Intraparenchymal and subarachnoid hemorrhages may be presenting or associated radiographic features of CNS vasculitis [41] although they occur less commonly than ischemic lesions so noted in up to 40% of patients with PACNS as compared to hemorrhage that occurred in only 4% to 12% of patients [42-44]. There is uncertainty regarding the significance of microscopic hemorrhage in patients with CNS vasculitis. T₂-weighted gradient-echo MRI, which depicts chronic blood or hemosiderin products as regions with marked signal intensity loss (susceptibility effect), was useful in demonstrating multiple silent petechial hemorrhages scattered throughout both cerebral hemispheres located in cortical-subcortical regions in a patient with stereotypic tingling spells in the right hand followed by acute mutism due to histological-proven PACNS. Brain CT showed a small hematoma in the left parietal lobe and 1.5 T T₁-weighted, turbo spin-echo T₂-weighted, and fluid-attenuated inversion recovery brain MRI demonstrated acute hemorrhage in the left parietal lobe as well as subacute hemorrhage in the right frontal lobe [42]. However, T₂-weighted gradient-echo images showed multiple small hemorrhages scattered throughout the cerebral hemispheres located in the cortical-subcortical regions sparing the basal ganglia, thalamus, and brain stem. Conversely, neither large nor small silent cortical hemorrhages were found among 25 patients with intracranial vasculitis employing T₂*-weighted MRI [45].

Leptomeningeal enhancement by MRI was noted in up to 9% of patients with PACNS [34, 44] often in association with cognitive disturbances, normal MRA and catheter angiography (CA), granulomatous angiitis histopathology and small vessel involvement [44].

Delayed perfusion and reduced cerebral blood volume may be seen on brain CT and MRI in patients with cerebral vasculitis [34, 45, 46]. Magnetic resonance spectroscopy (MRS) reveals elevated glutamate and glutamine levels and reduced N-acetyl aspartate content in cerebral vasculitis [46, 47], and absence of a choline peak [46-47].

High Resolution Magnetic Resonance Imaging

High resolution MRI (hrMRI) employing gadolinium enhanced fat-saturation T₁ spin echo techniques provides useful information of possible inflammatory changes in those with

suspected systemic LVV. More recently the use of vessel wall imaging has increased due to the multiple applications in vivo such as the differentiation between atherosclerosis and vasculitis, the visualization of intracranial dissection and to determine which aneurysm has ruptured in patients with acute subarachnoid hemorrhage and multiple aneurysms. The arterial wall enhancement in patients with vasculitis is probably related to contrast leakage from the lumen into the arterial wall given the increased permeability of the endothelium; it is also possible that the presence of dilated neovessels in the wall is responsible for the increased contrast enhancement. It is important to keep in mind that there may be a discordance between the MRI findings and the clinical vasculitis activity [48]. In 26 patients with TAK and 16 healthy subjects so studied [49], contrast-enhanced T₁-weighted spin echo MRI using small fields of view and thin slices showed enhancement of thickened aortic wall compared with myocardium suggested active TAK. The degree of disease activity was concordant with laboratory measures of disease activity in 88.5% of patients, including erythrocyte sedimentation rates and C-reactive protein. The measured signal intensity of the aortic wall relative to that of myocardium during the early phase of contrast-enhanced MRI, which was significantly correlated with serological markers of inflammation, provided a useful assessment of disease activity in TAK. Notably T₂-weighted signal intensity changes were less sensitive than enhanced images. In sixty-four consecutive patients with suspected GCA, Bley and colleagues [50a] assessed mural thickness, lumen diameter, and mural contrast-enhancement scores by T₁-weighted spin-echo images with sub-millimeter in-plane spatial resolution. Their findings demonstrated that evaluation of the mural inflammatory MRI signs for diagnosing vasculitis resulted in a sensitivity of 80.6% and a specificity of 97%, in comparison to histologic results alone which demonstrated a sensitivity of 77.8% and specificity of 100%. Some positive MRI results were associated with biopsy-negative histopathology for GCA presumably due to sampling errors with skip lesions predominating in the tissue biopsy. Among GCA patients who received treatment with corticosteroids <10 days, sensitivity of hrMRI ranged from 81% to 85% while others receiving corticosteroids >10 days demonstrated a sensitivity of 33%. Notwithstanding, hrMRI still should provide sensitive and specific information when neuroimaging is performed within days following the initiation of immunosuppressive treatment. Additionally, in GCA, Geiger et al. demonstrated how mural contrast enhancement of the ophthalmic arteries can be demonstrated using a 3 T MRI examination and they showed that it is a common finding in patients with GCA with suspicious ophthalmic arteries involvement.

High-resolution MRI findings of intracranial vasculitis include concentric and asymmetric vessel wall thickening, an eccentric or narrowed vessel lumen and vessel wall enhancement. Enhancement may be limited to the vessel wall or extend to adjacent leptomeninges. Kuker and colleagues [50b] reported that 25 of 27 (92.5%) children and adults patients with a diagnosis of cerebral vasculitis affecting large brain vessels secondary to various etiologies demonstrated mural thickening, 23 of whom had abnormal mural enhancement confirmed in more than one plane of imaging. The authors contended that for intracranial large vessel disease, direct vascular wall inflammatory wall changes provided greater specificity than indirect luminal imaging findings and perhaps exceeded that of tissue biopsy. Obusez and coworkers ([50c] suggested that the degree and persistence of vessel wall enhancement helped to differentiate PACNS and RCVS in a cohort of 26 patients with respectively confirmed diagnoses. Whereas mural enhancement was less prominent in RCVS and resolved in nearly all patients restudied at mean followup of 3.5 months, those with

PACNS demonstrated an increased degree of vessel wall enhancement with persisted over a mean followup of 13.5 months.

An additional role of wall imaging MRI is to help selecting the appropriate target for biopsy in cases of suspected vasculitis [48].

Indirect Vessel Imaging Techniques

Indirect imaging techniques that characterize changes in the vessel lumen leading to ischemia, infarction and hemorrhage in cerebral vasculitis can be obtained by MRA, CTA and CA, however these do not provide direct evidence of the associated underlying mural and perivascular inflammation. Catheter angiography provides up to 0.2 mm of spatial resolution and 0.5 to 0.25 seconds of temporal resolution in a typical study, exceeding MRA and CTA [30]. The spatial resolution of multi-detector CTA, which is dependent on detector row thickness, is approximately 0.4 to 0.75 mm. CA provides detailed information regarding hemodynamics that is generally absent from both CTA and MRA. Dynamic 320-section CTA provides limited hemodynamic information with a temporal resolution of 1 second and a spatial resolution of 0.5mm [51]. Indices for MRA spatial resolution are even less precise than these other techniques.

Magnetic Resonance Angiography

This non-invasive non-ionizing indirect vessel wall imaging study does not require intravenous contrast administration for the assessment of intracranial stenoses and vascular occlusions in suspected CNS vasculitis. MRA may overestimate vascular stenosis secondary to diminished signal intensity from vessel tortuosity and slow flow. The more subtle finding of intracranial vessel irregularity is more difficult to assess due to lower spatial resolution. Among nine arteries from 14 young patients with clinical and radiological suspicion of cerebral vasculitis, the sensitivity for detecting a stenosis by three-dimension (3D) TOF MRA or DSA varied from 62% to 79% for MRA, and 76% to 94% for DSA. The specificity for detecting a stenosis varied from 83% to 87% for MRA, and 83% to 97% for DSA. Using the criterion of >2 stenoses in two or more separate vascular distributions as a true positive criterion for cerebral vasculitis, the false positive rate for MRA and DSA were comparable [52]. When more than two stenoses were noted on MRA, DSA is unlikely to add further diagnostic precision in a given patient with suspected cerebral vasculitis, but yet might be useful when MRA was normal or disclosed <3 stenoses [52].

Computed Tomography Angiography

Indirect vessel wall imaging employing CTA has been used in TAK, GCA, PAN and CNS vasculitis. The efficacy of CTA in TAK, a chronic idiopathic LVV that primarily affects large vessels such as the aorta and its major branches, as well as the pulmonary and coronary arteries, is well established [53]. Non-specific inflammation of involved vessels leads to concentric wall thickening, fibrosis and thrombus formation. These produce the characteristic neuroradiologic findings of focal stenosis, occlusion, dilatation and luminal irregularity with a characteristic distribution and severity of involvement. The relative sensitivity and specificity of CTA for TAK was respectively 93% to 95% and 98% to 100% [54]. The salient CTA

features of TAK include mural thickening, luminal changes, collateral vessels, and other findings usually with respect to the pulmonary and coronary arteries. In the early stages of TAK mural inflammatory changes may precede luminal contour changes, an important advantage of CTA as compared with DSA.

CTA is useful in patients with GCA in whom LVV occurs in 25% of patients [55], especially in those with confirmed biopsy pathology to screen for the presence of stenosis, dissection, and aneurysms, as well as to assess the extent of arterial involvement and to monitor vascular lesions for signs of progression [56]. Intramural leaky microvessels which give rise to delayed enhancement of the arterial wall are consistent with, but not specific for inflammatory vasculopathy. Moreover, generally irreversible wall thickening and increased intra-wall blood pooling despite immunosuppressant treatment should not be employed to assess the inflammatory burden or disease activity [56]. Aneurysm formation along gastrointestinal, renal arteries and other systemic medium sized vessels so noted on CTA, particularly in the absence of aortic involvement, are useful neuroradiologic signs of PAN in the differential diagnosis of GCA [57, 58].

An entity considered by some to be part of the GCA spectrum, and often diagnosed with a CTA of the neck, is carotidynia, a clinical entity described first in 1927, which manifests with tenderness and pain at the neck at the level of the carotid bifurcation. The two clinical signs of carotidynia are not specific, and other causes of neck pain can have the same clinical presentation. This entity is thought to be caused by perivascular inflammation as proved by the common coexistence of increase of the erythrocyte sedimentation rate or C-reactive protein as well as ipsilateral lymph node enlargement and pharyngeal or laryngeal inflammation, as well as biologic findings, with a mild increase of the erythrocyte sedimentation rate or C-reactive protein. The findings on CT are presence of a perivascular infiltration, defined as soft amorphous tissue replacing the fat surrounding the carotid artery.

A relationship with GCA has not been demonstrated but in a series of 47 patients, 8 patients had an autoimmune disease such as rheumatoid arthritis, systemic lupus erythematosus, ankylosing spondylarthritis, Graves disease, Sjögren syndrome, or Hashimoto thyroiditis, often presenting during clinical relapse of the primary autoimmune disease [59]. A new name for the condition was recently proposed, Transient Perivascular Inflammation of the Carotid artery (TIPIC) syndrome [59].

CTA also provides useful assessment of stenotic, dilated and focally occluded vessels of the circle of Willis in the 2nd and 3rd order branches of the ACA, MCA and PCA involved by CNS vasculitis. However the resolution of luminal irregularity is less well appreciated on CTA compared with CA, since the former modality which is less dynamic, and requires the inference of collateral flow and angio-architecture from opacified vessels. The radiation dose penalty, which is slightly greater than a routine head CT, makes CTA suitable as an initial screening modality for CNS vasculitis in adults, but less desirable in children and young adults. CT readily identifies abnormal mural thickening as defined by thickness >1 mm in 93% of patients with clinical evidence of TAK along the ascending aorta, aortic arch, and descending thoracic aorta [53]. Up to 73% of patients with TAK so studied demonstrated changes within the cervicocerebral vessels, most commonly the arch and descending thoracic aorta, brachiocephalic artery and common carotid artery where wall thickening varied from 1 mm to 10 mm. Once considered the gold standard for detecting abnormal vasculature, CA may be falsely negative in the early stages of TAK [47, 53]. This is an important consideration as the disease is most effectively treated with immunosuppressive therapy during the earliest phase of the illness; a time when CA may be non-diagnostic. CTA is an

excellent option in these circumstances as it provides not only information regarding luminal abnormalities, including stenosis, occlusion, aneurysmal dilatation and contour irregularities similar to CA, but direct diagnostic findings including wall thickening, calcification and abnormal enhancement [47, 53]. While nonspecific to the cerebrovascular circulation, Yamada and colleagues [54] demonstrated a sensitivity and specificity of 95% and 100% respectively, for CTA in the diagnosis of TAK, with claims of positive correlation of vessel wall changes to the histopathologic findings [47]. Heterogeneous mural enhancement and an inner concentric low attenuation ring that enhanced at delayed imaging likewise demonstrated a positive correlation with the acute phase of histopathologic findings of vascularization and intimal swelling in the tunica media.

Catheter Angiography

Although CA has been the gold standard for diagnosis of cerebral vasculitis, it occupies a less important role compared to MRA and CTA in the initial evaluation of suspected patients. The classical angiographic features of CNS vasculitis are multifocal luminal narrowing, vascular contour irregularity and vascular dilatations with the appearance of a string of beads often along multiple vessels and in differing vascular territories, although ectasia and normal luminal diameter may also occur. The affected vessel may demonstrate a smooth or irregular luminal contour and vascular stenosis which is classically a discrete short segment or elongated. The size of the vessels affected and the distribution of lesions within each of the vessels varies with the vasculitic etiology and may be a clue to the proximate cause. Extracranial large vessel narrowing and undulation of long segments with variable luminal angiographic involvement occurs in GCA, while variable intracranial skull based and medium cortical vessel involvement occurs in anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAV), SLE and PACNS. There is no predilection for vessel branch points in PACNS in contrast to atherosclerosis and hypertensive disease [59]. Luminal narrowing along vascular regions of laminar flow disruption and high shear stress in the ICA bulb, petro-cavernous junction and cavernous segments suggests atherosclerosis. However, multifocal stenosis and luminal irregularity within the same vessel segment with intervening normal vessel contours, and isolated stenosis within separate vascular territories and otherwise normal vessel contours favors vasculitis. Multiple emboli generally present with more obstructive than stenotic lesions, and tends not to occur as discretely along multiple vascular territories or in tandem along the same vessel in contrast to CNS vasculitis. Angiographic features that favor medium vessel vasculitic involvement due to systemic vasculitis and autoimmune disease in contrast to PACNS include abrupt vascular truncation, occlusion and microaneurysm formation [60]. The collateral circulation should be investigated and quantified by CT and MR perfusion imaging in patients with severe luminal narrowing and vascular occlusion of medium and large vessels as should abnormal cerebral hemodynamics typified by slow anterograde flow, diminished distal luminal size, and prolonged circulation time. Vascular dissection which rarely occurs in intracranial vasculitis is much more common in the extracranial vasculature in GCA.

The sensitivity of CA for PACNS is reportedly 40% to 100% [34, 35, 38, 40, 59-63] and the specificity no higher than 37% for CA in the diagnosis of PACNS [64]; however they may vary depending upon the particular clinical, radiographic and histopathologic definitions employed. Vasculitic small vessel involvement is typically beneath the resolution of CA. Children with so-called angiography negative, biopsy positive, small vessel (SV)-childhood

PACNS (cPACNS) [65] who present with negative angiography and a positive MRI, are generally considered to be candidates for cerebral and leptomeningeal biopsy to confirm the presence of vasculitis.

There is a poor correlation between neuroradiologic findings on MRI and CA in PACNS [38, 60]. Whereas two-thirds of lesions detected by MRI showed a CA lesional correlate, only 44% of those detected by CA were conversely identified by MRI. Furthermore, the correlation of 41 territories involved by MRI subsequently studied by CA was 15%, whereas among 50 vascular territories involved by CA, a correlate was found in 34% of MRI studies.

The risk of transient neurological injury is 10% and permanent morbidity occurs in about 1% of patients undergoing CA for the evaluation of CNS vasculitis [66]. Intravenous corticosteroids administered prior to CA may ameliorate the risk of injury and reduce complications.

NUCLEAR MEDICINE IMAGING MODALITIES

Positron Emission Tomography

Nuclear Medicine evaluation of neurovasculitis remains promising but problematic. Conceptually the ability to monitor metabolic activity within the vessel wall should be a good indicator of inflammatory activity. ¹⁸fluorodeoxyglucose positron emission tomography (FDG-PET) has been the best studied radionuclide for this indication, particularly in systemic LVV. One meta-analysis [67] demonstrated a wide variability of diagnostic sensitivity for TAK ranging from 28% to 100% while the range of specificity was 50% to 100%. Fused PET and CT images provide superior anatomic localization and improved sensitivity and specificity of 91% and 89% for TAK. A greater diagnostic sensitivity of 80% and specificity of 89% in those studied by FDG-PET were noted for GCA [68]. Nonetheless, the specificity of FDG-PET is degraded by the presence of atherosclerosis as active inflammatory plaques may produce false positive findings [69]. The utility of FDG-PET for monitoring disease activity in these patients may be problematic. Some patients with TAK deemed inactive by clinical criteria may in fact demonstrate biopsy-proven active inflammation [70]. Studies indicate that FDG-PET is a sensitive and helpful diagnostic study for identifying patients with subclinical active disease, with 83% of biopsy-proven GCA patients demonstrating positive or concordant lesions by FDG-PET imaging [71]. The sensitivity and specificity of FDG-PET in the identification of active vasculitic disease compared with clinical signs and laboratory criteria led to respective rates of 100% and 89% [72].

Single Photon Emission Computed Tomography

Single photon emission computed tomography (SPECT) employs multiplanar nuclear medicine imaging for the investigation of regional CNS perfusion abnormalities. It provides direct information about the pathophysiology and cerebral metabolism in cerebral vasculitides at the level of capillary endothelium in the blood-brain barrier (BBB) microcirculation beyond the resolution of MRA, CTA, and CA [73, 74].

There are claims of the utility of brain SPECT imaging in the clinical diagnosis and management of cerebral vasculitis associated with SLE [75, 76], Kawasaki disease [77], IgAV [78], neurological BD [79], GPA [80], and brain irradiation [81, 82]. Apart from the direct impact of vascular narrowing and occlusion resulting from necrotizing arteritis and vascular infiltration, other explanations for an abnormal brain SPECT include circulating immune complexes on the BBB [83], and neurotoxic effects of antibodies and brain antigenic targets [81], glial cell interactions [82], and pathogenic hypersensitivity responses to brain antigens released during vascular-mediated tissue necrosis [82].

The results of brain SPECT imaging were described in one patient with histologically-verified cerebral vasculitis [84]. This 71-year-old man with later-proven granulomatous angiitis of the brain underwent Tc-99m hexamethylpropyleneamine oxime (HMPAO) brain SPECT three weeks after onset of CNS disease. There was irregular radiotracer uptake throughout both cerebral hemispheres with scattered multiple areas of hypoperfusion, further demonstrated in surface volumetric images. Postmortem examination showed fibrinoid necrosis, inflammatory cells, mainly lymphocytes, histiocytes and a few multinucleated giant cells involving medium-to-small meningeal and parenchymal vessels with intramural vascular deposits of amyloid, without systemic vasculitis. Although there was no specific mention of the correlation of the SPECT findings with anticipated BBB involvement, the authors [88] attributed the observed cortical hypoperfusion to focal narrowing and occlusion of small- and medium-sized cerebral arteries.

Color Doppler Ultrasonography

Color Doppler ultrasonography (CDU) and color duplex imaging provide direct imaging and evaluation of superficial arteries and their vessel walls. They have been most extensively studied in systemic LVV such as GCA and TAK. This non-invasive methodology which lacks exposure to ionizing radiation can be easily administered and repeated to monitor disease activity and response to treatment. It provides a high resolution imaging of the walls of deep-seated vessels as compared with MRI, detecting wall thickness and edema the latter of which produces a hypoechoic signal on CDU as a halo sign. In a meta-analysis of 998 patients with 17 studies, the sensitivity of the halo sign for biopsy-proven GCA was only 75%, but specificity was 83%. Concentric homogeneous mural thickening, stenosis and occlusion of the aorta and brachiocephalic branches are typical CDU features of GCA and TAK [69, 85, 86], which may be differentiated from atherosclerotic disease by the absence of plaque formation, concentric long segment involvement and location. Ultrasonography revealed subtle mural changes characterized by a homogenous, circumferential mid-echoic wall thickening within the subclavian and carotid arteries in the early stages of TAK preceding abnormalities detected by CA [87], with overall greater wall thickness of the CCA and ICA in the vasculitic vessels compared to controls. The CCA intima to medial thickness ratio was increased in patients with TAK compared with normal control [88] yielding respective sensitivity and specificity rates of 82% and 70%.

The wall diameters of common, frontal and parietal division of the superficial temporal artery were significantly greater in patients with GCA than in symptomatic patients without the disease as well as asymptomatic age-matched controls [89]. A hypoechoic halo

surrounding a patent vessel lumen was found in 73% of biopsy proven vasculitis patients but not in symptomatic patients without GCA and asymptomatic controls. The histopathologic finding of mural cellular infiltration did not correlate with a hypoechoic halo albeit attributed to edema. The halo disappeared at a mean of 16 days following effective treatment. Similar findings are present in the occipital arteries [90] although the sensitivity is less when compared with the superficial temporal arteries. The halo examination is a useful exam for symptomatic patients presenting with nuchal pain, occipital headache or occipital scalp tenderness, especially when occipital artery involvement may be the only imaging manifestation of the disease.

CONCLUSION

The neuroimaging evaluation of vasculitis may seem complex and nonspecific, particularly for PACNS and the primary systemic autoimmune vasculitides. When all imaging modalities including those that provide parenchymal, luminal and mural evaluation are brought to bear on a given patient with suspected vasculitis, the entire constellation of findings typically brings clarity to the situation. The largest single series of PACNS [35] demonstrated that 77% of CT, 97% of MRI, 59% of MRA and 90% of CA studies were ultimately positive in comparison to 62% of positive brain biopsies. While each individual modality may be nonspecific, combining CNS parenchymal and peripheral vascular radiological studies with serological and histopathologic studies in clinically suspected patients, should assure the accurate diagnosis of systemic and nervous system vasculitis in virtually all true cases.

Chapter 218

ADULT PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM AND RELATED SYNDROMES

Rula A. Hajj-Ali, MD and Leonard H. Calabrese*, DO

Cleveland Clinic Lerner College of Medicine of Case Western Reserve University,
Center for Vasculitis Care and Research, Cleveland Clinic Foundation,
Cleveland, Ohio, USA

ABSTRACT

Primary angiitis of the central nervous system is one of the most complex and serious forms of central nervous system vasculitis. Adding to the challenge of diagnosis and recognition in the absence of predictive non-invasive laboratory tests, research into this disorder is limited by the scarcity of human pathological material and absence of an animal model. Nonetheless, there have been significant advances in the recognition of the clinical heterogeneity of the disorder and the differentiation from those that may mimic it. This chapter reviews the epidemiological, clinicopathologic, diagnostic laboratory and therapeutic aspects of primary angiitis of the central nervous system.

INTRODUCTION

Primary angiitis of the central nervous system (PACNS) is a vasculitic disorder confined to the brain, spinal cord, and its coverings. It is differentiated from secondary forms of CNS vasculitis most often due to concomitant or undying infection, connective tissue disease, or primary systemic vasculitis, and other disorders that may mimic it. Adult [1] and childhood PACNS (cPACNS) [2], primary CNS vasculitis (PCNSV) [3], granulomatous angiitis of the brain (GAB) [4], CNS (GACNS) or nervous system (GANS) [5], and isolated angiitis of the CNS (IACNS) [6], are roughly equivalent terms for a prototypical primary vasculitic disorder restricted to the CNS of diverse cause and clinicopathologic expression.

The past decade has witnessed renewed interest in PACNS since the first description of PACNS by Calabrese and Mallek [7] of eight patients from the Cleveland Clinic Foundation patients, two of which included children age 10 and 12 years. Selection criteria for the definite diagnosis of PACNS [7] included a history of clinical findings of an acquired neurological deficit that remained unexplained after a thorough initial basic evaluation, and demonstration of classic angiographic or histopathologic features of CNS angiitis without evidence of systemic vasculitis or another disorder to explain the observed laboratory findings. These criteria were expanded by Benseler and colleagues [8] to include children age 18 years or less with neurological or psychiatric involvement, emphasizing their unique neuropsychiatric and cognitive presentations. At least three reasons account for the renewed interest in PACNS. First, the recognition that cPACNS fit into the larger designation of inflammatory brain disease (IBD) [8, 9]; moreover, PACNS was the most frequently diagnosed IBD at the Hospital for Sick Children in Toronto between 1990 and 2012. Second, the inclusion of PACNS as a prototypical single organ vasculitis (SOV) in the 2012 Revised Chapel Hill Consensus Conference [10] so defined as vasculitic involvement of arteries or veins of a single organ without features to indicate the limited expression of a systemic vasculitis. Third, the formation of the French COVAC' Cohort, a collaboration of the French Vasculitis Study Group and French NeuroVascular and Internal Medicine Societies [11] of antemortem diagnosed PACNS cases available for prospective analysis.

This chapter reviews the epidemiological, clinicopathologic, diagnostic laboratory and therapeutic aspects of adult PACNS. This topic has been recently reviewed by the present authors [12].

BACKGROUND

Primary CNS vasculitis was first described by Harbitz in 1922 [13] in two patients, one with worsening headaches, mental change, and ataxia culminating in stupor, spastic paraparesis, coma and death in 2 years; and a second patient with hallucinations and confusion progressing to gait difficulty, stupor, coma and death in nine months. Granulomatous vasculitis of the meninges comprised of lymphocytes, multinucleated giant cells and epithelioid cells with vessel necrosis and extension into the brain along involved veins and arteries of varying caliber. Over the ensuing quarter century, additional patients were reported under the rubric of allergic angiitis and granulomatosis [14], giant cell arteritis [15] and even sarcoidosis [16]. Cravioto and Fegin [17] delineated the clinicopathologic syndrome of non-infectious granulomatous angiitis of the CNS, and for two more decades, rare affected patients were identified in life. The identification of angiographic beading of cerebral vessels at sites of presumed arteritis was first noted by Hinck and coworkers [18] in cases of giant cell arteritis (GCA), and later by Cupps and Fauci in IACNS [6]. In the same year, 1988, that Calabrese and Mallek [7] proposed unifying criteria for the antemortem diagnosis of PACNS, Younger and colleagues [4] described clinicopathologic heterogeneity of postmortem proven cases.

Calabrese and colleagues [19] and later Singhal [20] separated PACNS from the most common mimickers of PACNS, the angiographically-defined variants of reversible cerebral angiopathy including benign angiopathy of the CNS. By 2007, these reversible syndromes

were combined into a separate nosology termed the reversible cerebral vasoconstriction syndromes (RCVS) [21], the diagnosis of which was clinically suggested by sudden, severe thunderclap-like headache with or without associated neurological deficits, and reversible angiographic findings not due to true vasculitis. In the same year, Salvarani and colleagues [3] reported a large cohort of more than 100 patients with primary CNS vasculitis (PCNSV) from a single center based upon the criteria of Calabrese and Mallek for PACNS [7], delineating clinicopathological subsets of heterogeneous disease. The importance of the accurate definition of disease employing the criteria of Calabrese and Mallek [7] was apparent in two forms of cPACNS, one with a predilection for small meningeal and penetrating cerebral vessels and unobvious cerebral angiographic features [9, 22], and another that affected medium-to-large named cerebral vessels in which angiographic features were readily apparent [8, 22, 23].

CLINICAL FEATURES

PACNS

PACNS affects patients of all ages with a peak at about 50 years of age and a more frequent occurrence among men than women. A retrospective analysis of 101 cases [3] revealed an average annual incidence of 2.4 cases per 1,000,000 million person-years. Although underdiagnosed in the setting of an evaluation for dementia, CNS vasculitis was found to be one of the common misdiagnoses of patients with presumed sporadic Jakob-Creutzfeldt disease [24]. The clinical signs and symptoms of PACNS are non-specific reflecting the diffuse and often patchy nature of the pathological process with a clinical course that varies from hyperacute to chronic and insidious. The most common presenting symptoms are headache followed by progressive focal neurologic deficits. The headache may vary in description, intensity and pattern, but is most often chronic and insidious. Thunderclap headache virtually never occurs in true PACNS and its presence should lead to a suspicion of RCVS [21]. Other symptoms including cognitive impairment, stroke and transient ischemic attacks, occurred in 30% to 50% of patients [3, 25]. Strokes are frequently multiple and vary in age and anatomic distribution, affecting both grey and white matter. Cranial nerve palsies occur rarely as may myelopathy, seizures, and ataxia. Constitutional symptoms and signs such as weight loss and specific organ-related disease are atypical in PACNS and when present suggests a systemic inflammatory process. PACNS should be strongly considered when there are multiple areas of cerebral ischemia affecting different vascular territories in association with an inflammatory cerebrospinal fluid (CSF) profile; and subacute or chronic headache with cognitive impairment or chronic aseptic meningitis, especially after exclusion of infectious and neoplastic disorders.

GACNS

With less than a handful of such patients seen at our center per year, the epidemiology of the disease is poorly understood, but appears to be a male-predominant disorder that occurs at

virtually any age with a median of 50 years [25, 26]. Four patients with GACNS [4] were defined by the presence of granulomatous giant cell and epithelioid cell infiltration in the walls of arteries of various calibers from named cerebral vessels to small arteries and veins at postmortem examination. Whereas the typical patient with PACNS might present with headache of gradual onset accompanied by focal signs and symptoms, or rapidly progressive neurological deficits evolving over days, weeks, or months with seemingly prolonged periods of stabilization, those with GACNS present with headache, mental change, and elevated CSF protein content with or without pleocytosis. Headache was noted at onset in all four patients of one series of GACNS [4] and in 57% of literature patients, as well as, in the course of the disease in 78% of patients overall. Neuroimaging employing magnetic resonance imaging (MRI) typically shows multiple bilateral ischemic foci. The combination of a normal MRI and normal CSF examination carries a high negative predictive value for the diagnosis of GACNS whereas hemiparesis, quadriparesis, progressive lethargy and impending coma were associated with a poor prognosis and mandated the need for combined meningeal and brain biopsy to establish the diagnosis with certainty.

Salvarani and colleagues [3] diagnosed primary PCNSV in 31 patients by histopathology and 70 patients by angiography, in whom 18 had a granulomatous inflammatory pattern, 8 a lymphocytic pattern, and 5 an acute necrotizing pattern. Headache was the most common symptoms noted overall in 63% of patients, followed by abnormal cognition, hemiparesis and persistent neurological deficit. A granulomatous pattern of inflammation was seen most often in those with altered cognition and at an older age.

The diagnosis of GACNS is generally established by pathologic examination of the brain and leptomeninges that shows granulomatous giant cell and epithelioid cell vasculitis of the walls of arteries of various calibers from named cerebral vessels to small arteries and veins. Examination of antemortem leptomeningeal and brain tissue is vital to the exclusion of infectious, malignant, and other etiologies that may lead to a similar neuropathology. Although false-negative biopsy can occur in 25% to 50% of cases [27], the yield is enhanced when a radiographically abnormal area is targeted, and the specimen includes leptomeningeal tissue in addition to the brain parenchyma. The size of the vessels affected in GACNS is beyond the spatial resolution of cerebral angiography, which is typically normal in these patients.

Younger and colleagues [4] noted one patient each with non-Hodgkin lymphoma, sarcoidosis, Varicella-zoster virus (VZV) infection, and no associated disorder in their four cases. In a subsequent review of the cumulative literature up to 1997, the same authors [5] reported a new case of GACNS and described the clinicopathologic features of 136 published cases, 51 of which had concomitant lymphoproliferative diseases, VZV infection, amyloidosis, sarcoidosis, systemic lupus erythematosus, GCA, and human immunodeficiency virus type 1(HIV1) without the acquired immunodeficiency syndrome (AIDS). Whether such cases are equivalent to GACNS occurring *de novo* is unknown, but this analysis remains the basis of much of the clinical appreciation for this relatively rare disorder.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of PACNS and hence GACNS (Table 1) comprises primary and secondary arteriopathies that mimic the clinical and angiographic presentation of

PACNS. One category includes primary systemic vasculitis notably polyarteritis nodosa, anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis, Behçet disease, Cogan syndrome; and diverse connective tissue disorders such as systemic lupus erythematosus, Sjogren syndrome, and lymphomatoid granulomatosis, that can mimic PACNS, as may viral, bacterial, fungal and *Rickettsia* infections.

Malignant disorders such as primary CNS lymphoma, malignant angioimmuno-proliferative, carcinomatous and gliomatous brain tumors; and coagulopathies resulting from thrombotic thrombocytopenic purpura, subacute bacterial endocarditis, cardiac myxoma and embolism, can lead to confusion with PACNS, as may atherosclerotic diabetic, dyslipidemic and hypertensive cerebral arteriopathy, moyamoya disease, intracranial dissection, and fibromuscular dysplasia. Genetically inherited disorders including Susac syndrome, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) and the autosomal recessive variant CARASIL, retinal vasculopathy with cerebral leukoencephalopathy (RVCL), may also have a clinical presentation similar to PACNS.

Table 1. Differential diagnosis of PACNS

Primary Systemic Disorders
<i>Vasculitis</i> : PAN, MPA, GPA, EGPA, BD, CS
<i>Connective Tissue Disease</i> : SLE, Sjogren syndrome, sarcoidosis, lymphomatoid granulomatosis
Infection
Viral, bacterial, fungal, <i>Rickettsia</i>
Malignancy
Angioimmunoproliferative disorders, carcinomatous meningitis, infiltrating glioma, malignant angioendotheliomatosis, PCNSL
Arterial Vasospasm
Primary: RCVS
Secondary: Pheochromocytoma, aneurysmal subarachnoid hemorrhage
Hypercoagulation
Thrombotic thrombocytopenic purpura, embolism, subacute bacterial endocarditis, cardiac myxoma, paradoxical emboli; APL
Other Cerebral Arteriopathies
Moyamoya disease, cerebrovascular atherosclerosis, arterial dissection, fibromuscular dysplasia
Demyelination
Demyelinating disease
Radiation
Radiation vasculopathy
Genetically Inherited
RVCL, Susac syndrome, NF, MELAS, CADASIL, CARASIL

Abbreviations: PAN, Polyarteritis nodosa; MPA, Microscopic polyangiitis; GPA, Granulomatosis with polyangiitis; EGPA, Eosinophilic granulomatosis with polyangiitis; BD, Behçet disease; CS, Cogan syndrome; SLE, Systemic lupus erythematosus; PCNSL, Primary CNS lymphoma; RCVS, Reversible cerebral vasoconstriction syndrome; APL, Antiphospholipid syndrome; RVCL, retinal vasculopathy with cerebral leukodystrophy; Susac syndrome, Encephalopathy, branch retinal artery occlusions and sensorineural hearing loss; NF, neurofibromatosis; APMPE, Acute posterior placoid pigment epitheliopathy and cerebral vasculitis; MELAS, Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes; CADASIL, Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CARASIL, Cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy.

Table 2. Essential elements for RCVS

1. Thunderclap headache with or without other neurological signs and symptoms
2. No evidence of aneurysmal subarachnoid hemorrhage
3. Normal or near normal cerebrospinal fluid analysis
4. Reversible cerebral segmental vasoconstriction involving arteries of Circle of Willis documented by serial angiography, CTA, MRA or a flow-related vascular study such as TCD within 12 weeks of onset

Abbreviations: RCVS, Reversible cerebral vasoconstriction syndrome; CTA, Computed tomography angiography; MRA, Magnetic resonance angiography; TCD, Transcranial Doppler.

However, RCVS [21, 28-31], and related disorders sharing a similar clinical phenotype of reversible cerebral artery vasoconstriction, may be indistinguishable from PACNS arteritis. The diagnostic criteria of RCVS (Table 2) include: 1) thunderclap headache with or without other neurological signs and symptoms, 2) absence of aneurysmal subarachnoid hemorrhage, normal or near-normal CSF profile, 3) reversible segmental vasoconstriction involving arteries of Circle of Willis documented by serial angiography, CTA, MRA or a flow-related vascular study within twelve weeks of onset of the presentation, and 4) resolution in 60 days. Subarachnoid and intracerebral hemorrhages were usually encountered in the first week of onset respectively in 34% and 20% of cases, and typically along the cerebral convexity. Ischemic infarction ensues in 39 % of patients with RCVS during the second week from onset of symptoms along watershed areas between the anterior and posterior circulations, so noted as multiple, bilateral and symmetrical lesions with or without associated cerebral edema [29, 30]. Clues to the differentiation of RCVS and PACNS include a history of vasoconstrictive drug exposure or recent childbirth and thunderclap rather than insidious or chronic headache in the former, with normal or near-normal CSF however both may demonstrate seizure, strokes, and abnormal cerebrovascular imaging. Neuroimaging is rarely normal in PACNS and infarcts tend to be ischemic, infrequently hemorrhagic, while RCVS manifests severe vasoconstriction without parenchymal lesions, alternatively lobar and cortical surface subarachnoid hemorrhages or reversible edematous lesions characteristic of the ‘posterior reversible leukoencephalopathy syndrome.’ The angiographic abnormalities in RCVS are typically more dynamic, severe, and resolve over weeks to 3 months. High-resolution MRI holds promise in differentiating RCVS from CNS vasculitis based upon the presence and the pattern of concentric and eccentric vessel wall contrast enhancement [32]. Nonetheless, differentiation of the two disorders may remain uncertain when other studies supporting PACNS including brain biopsy are falsely negative.

LABORATORY EVALUATION

Blood Studies

The diagnostic workup in PACNS, which may be extensive, covers a wide range of modalities reflective of the intrinsic lack of test specificity for this diagnosis. Peripheral blood counts, chemistries, acute phase reactants and inflammatory markers such as the C- reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are expectedly normal but useful to obtain to exclude an underlying or concomitant systemic inflammatory process. Although there are no specific serologic markers for PACNS it is useful to obtain antinuclear antibody

(ANA), ANCA, serum complement levels, antiphospholipid (APL), baseline coagulation studies, as well as acute and convalescent infectious antibody titers as may be suggested by epidemiological, host immune factors and exposure history.

Cerebrospinal Fluid

It is imperative to perform a lumbar puncture to analyze the CSF unless otherwise contraindicated especially to exclude infection and malignancy; and in GACNS, the majority of affected patients will demonstrate elevation of the protein level and lymphocytic pleocytosis, however in either disorder, neither the white blood cell count nor protein level will respectively exceed 250 cells/mm³ or 500 mg/dL [25, 33, 34]. Emerging molecular techniques with next generation sequence applied to CSF provide an unbiased approach to identify infectious etiologies in patients with possible CNS vasculitis [35].

Magnetic Resonance Imaging

The reported sensitivity of MRI in PACNS, which has been 75% and approaching 100% [1] in the detection of cautive lesions, may not be reliable due to the erroneous inclusion of patients with RCVS. Cerebral infarction, the most common lesion seen on MRI, was noted overall in 53% of patients with PACNS [1], and often multiple, affecting the cortical and subcortical parenchyma; with nonspecific high-intensity T₂-weighted white matter FLAIR lesions [1]. Mass lesions occur in up to 5% of affected patients as do intracranial hemorrhage in 8% of patients. Collectively, abnormalities of CSF and MRI are noted in close to 100% of those with GACNS which then when normal, generates a high negative predictive probability for the diagnosis of GACNS [36].

Cerebral Angiography

The expected cerebral angiographic findings of PACNS are alternating areas of stenosis and dilatation that resemble beads on a string, which may be smooth or irregular in appearance, bilateral or involve single named vessels [37]. Other angiographic findings include tapering of the vessel lumen of a single vessel or multiple vessels. However, these angiographic findings are non-specific and can be observed in nonvasculitic atherosclerosis, radiation vasculopathy, fibromuscular dysplasia, infection, and especially RCVS. Moreover, the reported specificity of 30% of cerebral angiography in the diagnosis of PACNS suggests the need for further work-up to rule out other mimicking conditions when the typical angiographic features for vasculitis are not observed [37]. The sensitivity of direct cerebral angiography exceeds that of brain MRA, however the spatial resolution falls in vessels <500 μm in diameter. Accordingly, higher false negative results should be expected in the setting of known small vessel vasculitic pathology such as GACNS and angiography-negative small vessel cPACNS. High-resolution vessel wall MRI, which provides detail of vessel lumina and

wall structure, has the capacity to increase the test specificity of non-invasive vascular neuroimaging in CNS vasculopathy [32].

Brain Biopsy

Pathologic examination of the brain is still the gold standard for the diagnosis of PACNS because of its ability to confirm the diagnosis of PACNS and more importantly exclude PACNS mimics [38]. Special stains are useful to examine for malignancy and as are tissues culture for infectious etiologies of secondary CNS vasculitis. A non-diagnostic or negative biopsy does not rule out PACNS, and false-negative biopsy results, that can be as high as 25% of autopsy-documented cases [38] are due to patchy vasculitic involvement and potential inaccuracy of a non-lesional biopsy sample. The microscopic appearance of GACNS includes segmental necrotizing multinucleated giant cell and epithelioid granulomatous vasculitic involvement of small to medium-sized arteries in the leptomeninges and cortex, with involvement of veins in about one-half of cases. Not all of these features are present in all patients, and the distribution of lesions may be patchy in the CNS. Although loosely formed granulomatous giant cell lesions may be encountered, well-formed granulomas are more commonly observed, with up to 20% of cases demonstrating lymphocytic inflammation of vessel walls without prominent granulomas [38]. Tissue biopsy should ideally be performed through open craniotomy with sampling of both leptomeningeal and parenchymal brain tissue at abnormal sites suggested by neuroimaging, and if inaccessible, along the temporal tip of the non-dominant hemisphere [38].

TREATMENT AND PROGNOSIS

Rheumatologists and neurologists treating adult patients with PACNS must choose their treatment from among available immunosuppressant and biological agents without the benefit of randomized-controlled clinical trials however the literature does provide some guidance. The historical basis for the use of aggressive immunosuppressant therapy for CNS vasculitis commenced with the reports of the efficacy of combination immunosuppressant therapy employing oral corticosteroids and intravenous cyclophosphamide by Cupps and coworkers [6, 27], and later Moore [40] who ascertained the diagnosis of CNS vasculitis based upon the clinical criteria of a clinical pattern of headache, multifocal neurological deficits and cerebral angiography demonstrating segmental arterial narrowing, with exclusion of systemic inflammation and infection and proof of vascular inflammation in a leptomeningeal or parenchymal biopsy tissue. Empiric therapy with corticosteroids and cyclophosphamide was advocated at doses similar to that employed for granulomatosis with polyangiitis [41] in all five patients in the series by Moore [40] even though brain or leptomeningeal biopsy showed unequivocal evidence of cerebral vasculitis in only two patients, and non-diagnostic perivascular inflammation in three others. The author's explanation was that while useful in diagnosis and management, antemortem biopsy could be less striking and inconsistent. Prednisone alone appeared to have either a transient or no effect on the course of the disease process.

It has been suggested that historical surveys of PACNS might be misleading because of the bias of ascertainment, favoring the larger number of postmortem cases that proved fatal without treatment [5]. A meta-analysis of 54 literature patients comprising 30 patients diagnosed antemortem and 24 patients treated before postmortem confirmation [5] found equally satisfactory outcomes in those treated with corticosteroids alone or with oral cyclophosphamide, with overall improvement in 24 of 34 (70%) so treated. Three patients treated with corticosteroids and oral cyclophosphamide died due to serious sequela of the latter treatment. Although the findings appeared to challenge the imperative of aggressive empiric treatment, there is still agreement among experts [5] that cyclophosphamide can be safely employed in histologically-confirmed patients, especially those who continued to progress while on corticosteroids and can be closely monitored for medication related side effects.

Hutchinson and colleagues [42] described the treatment of small vessel PACNS in a single-center open-label childhood cohort. They employed cyclophosphamide at doses of 500 to 750 mg/m² monthly infusions for six months, followed by maintenance therapy of azathioprine 1 mg/kg/day and a target dose of 2 to 3 mg/kg/day, with mycophenolate mofetil titrated at dosages of 800 to 1200 mg/m²/day for up to 24 months. Outcome was rated using a pediatric stroke outcome measures (PSOM). Among 13 who completed the treatment regimen, nine had a good neurological outcome by PSOM scoring and four achieved remission of disease. Therapeutic guidelines remain informal, based upon expert opinions and historical bias suggesting that PACNS is progressive and uniformly fatal if left untreated [25].

In our experience, the majority of patients with documented GACNS should be treated with combination corticosteroid and cyclophosphamide therapy similar to systemic small vessel vasculitis algorithms [42, 43] to control the disease, implementing maintenance therapy with mycophenolate mofetil or azathioprine [1], and monitoring the activity of disease clinically and with serial MRI. All patients should receive prophylaxis for *Pneumocystis jirovecii* infection and followed for infections, osteoporosis, and other treatment-related complications [1], and followed by a team of health care professionals in rheumatology, neurology, neuroradiology, and physical therapy to ensure optimal care.

CONCLUSION

Adult PACNS is one of the most challenging and complex vasculitic disorders to diagnose and treat. Moreover, research into this disorder has been limited by the scarcity of human pathological material and absence of an animal model. There have been significant advances in the recognition of the clinical heterogeneity of the disorder and the differentiation from less fatal disorders that may mimic it.

INTRODUCTION

Primary central nervous system vasculitis (PCNSV) is a rare vasculitis that affects the brain and occasionally the spinal cord of adults and children [1]. Extensive progress has been achieved in the recognition of clinicopathological subsets that has translated into useful nosology reflective of the natural history and response to immunosuppressant treatment.

HISTORICAL BACKGROUND OF PRIMARY CNS VASCULITIS

The first case of PCNSV was described in 1952 by Newman and Wolf [2] and subsequently by Cravioto and Feigin [3] in 1959. The latter authors designated the disease as granulomatous angiitis of the nervous system (GANS) or granulomatous angiitis of the central nervous system (GACNS), because of the histologic granulomatous vasculitic changes

* The authors have nothing to disclose.

they observed. Cupps and Fauci [4], influenced by their advances in the classification, diagnosis, and treatment of systemic vasculitides at the National Institute of Health (NIH) [5], named the disorder isolated angiitis of the central nervous system (IACNS). Over the ensuing decades, PCNSV was relegated to the penumbra of vasculitis [6]. In 1988, Younger and colleagues [7] recognized the diversity in etiology due to association of some cases with neurosarcoidosis, non-Hodgkin lymphoma, or varicella zoster virus infection as well as the varied pathological expression which included arteries and veins of variable caliber both intracerebral and more distal leptomeningeal vessels. In the same year of 1988, Mallek and Calabrese [8] described the clinicopathological aspects, findings in diagnostic studies, and response to therapy in 8 Cleveland Clinic Foundation cases and a review of 40 patients in the literature. Headache was noted in 58% of entire group followed by hemiparesis in 35% of patients, mental impairment in 27%, dysphasia in 15%, seizures in 13% and ocular signs in 13%. Cerebrospinal fluid (CSF) was abnormal in 81% of patients. Two-thirds of patients who underwent conventional cerebral angiography manifested vascular changes consistent with cerebral vasculitis. Histopathologic confirmation of CNS vasculitis was available in 26 of 37 (74%) patients examined at postmortem examination, and in 10 of 14 (71%) of patients by antemortem brain biopsy with or without leptomeninges. Of the four patients with negative antemortem brain biopsy, one specifically did not include leptomeninges, and three others had demonstrable vasculitis of meningeal vessels at postmortem examination emphasizing the importance of obtaining combined brain and leptomeningeal tissue. Mortality was noted in 28 of 46 (61%) patients, however among the Cleveland Clinic Foundation patients, full resolution was achieved in six treated with combination corticosteroid and cyclophosphamide therapy, as well as in one patient each treated with high dose prednisone and another patient with only angiographic validation of vasculitis, who was untreated. These observations suggested an improved prognosis with an aggressive therapeutic approach as was previously proposed by Cupps and colleagues [4] and Fauci and colleagues [5]. Although not so stated, there was an obvious admixture of benign angiopathy in the patient who fully resolved without treatment. Calabrese and Mallek [8] proposed formal diagnostic criteria requiring fulfillment of three conditions: a history or presence of an acquired neurological deficit, histological or angiographic evidence of vasculitis, and lack of evidence of a systemic vasculitis or other conditions to which the angiographic or pathologic features could be attributed. The interchangeable term primary CNS angiitis (PACNS) like PCNSV, underscored the restricted nature of the illness, and like IACNS, emphasized the primary and often idiopathic nature of the disorder [9, 10] rather than the granulomatous pathology. The rationale was that giant cells and epithelioid cells, usually found at postmortem examination were inconstant findings in meningeal and brain biopsy tissue and therefore not necessary for antemortem diagnosis [11].

Later observations by Salvarani and colleagues in adults [12] would begin to unravel the clinicopathological dichotomy of granulomatous and non-granulomatous histology in adults beyond the simplistic assumption that granulomatous pathology was simply more lethal and found most often at postmortem examination than less fatal non-granulomatous changes so seen antemortem. Contemporaneously, PCNSV was described in two children with acute presentation of headache and focal neurological signs diagnosed by combined leptomeningeal and brain biopsy demonstrating non-granulomatous, non-necrotizing lymphocytic vasculitis predominantly affecting leptomeningeal arterioles, capillaries and venules [13]; and three others with acute headache and focal neurological deficits who died. In the latter three,

postmortem examination showed involvement of large named vessels by necrotizing granulomatous vasculitis including the distal vertebral [14], basilar [15], and middle cerebral artery [16] arteries. The clinicopathologic dichotomy of PCNSV in children was later summarized by Benseler and colleagues [17]. Angiographic large CNS vessel stenoses or occlusions in affected children caused strokes with manifestations of hemiparesis, hemifacial weakness, and hemisensory loss due to decreased perfusion in the area of the stenotic vessel and ischemia of the dependent brain territory. In contrast, distal CNS vasculitic and adjacent parenchymal inflammation led to diffuse neurologic deficits including headache, seizures, and subtle or overt cognitive, behavioral and personality changes. Those with both small- and large-vessel inflammatory vasculitic involvement might present with overlapping clinical deficits. Yet, in contrast to fatal adult PCNSV and the few fatal childhood cases [14-16], brain and meningeal biopsy performed in children at one center [18] with suspected vasculitis but negative angiograms revealed non-granulomatous, lymphocytic vasculitis of small vessels. This subset in children appears to be the fastest growing group of children with primary vasculitis at most centers [17].

SPECTRUM OF PRIMARY CNS VASCULITIS

The achievements of the 1980s proved to be the lessons for the 1990s. Although the acceptance and application of diagnostic criteria for PCNSV facilitated research and clinical studies alike, as the number of recognized patients increased, it became clear that PCNSV was more heterogeneous than previously thought. Moreover, enthusiasm for the empiric treatment of cerebral vasculitis waned as it became evident that cerebral angiography alone was insufficient for the diagnosis of PCNSV. This was noted in Case 3 of Calabrese and Mallek's 1987 paper [8] with angiographically diagnosed CNS vasculitis and full resolution without treatment. In later publications, Calabrese and colleagues [19-21] displayed the increasing awareness that patients who they earlier called "benign angiopathy of the CNS" (BACNS), represented a reversible cerebral vasoconstriction syndrome (RCVS) [21] and might be intermixed with angiographically-proven PCNSV due to common clinical and angiographic findings as shown in Table 1. By 1997, with 136 published cases of histologically-defined granulomatous CNS vasculitis alone [22] and the recognition that the criteria were performing poorly in discriminating PCNSV from RCVS, Calabrese and coworkers [21] proposed formal criteria for RCVS, the five critical elements of which included, transfemoral cerebral angiography or indirect computerized tomography angiography (CTA) or magnetic resonance angiography (MRA) documenting multifocal segmental cerebral artery vasoconstriction; lack of evidence for aneurysmal subarachnoid hemorrhage; normal or near-normal CSF with protein content <80 mg%, normal glucose content, and <10 mm³ leukocytes; development of acute severe headache with or without additional neurologic signs or symptoms; and reversibility of angiographic abnormalities within 12 weeks of onset. If death occurred before the followup studies were completed, postmortem examination should exclude vasculitis, intracranial atherosclerosis and aneurysmal subarachnoid hemorrhage, which might also manifest with headache and stroke similar to RCVS. The accuracy of cerebral angiography alone for detecting vasculitis was

estimated to be 50% to 90%, citing Salvarani and colleagues [12], when beading and interposed regions of ectasia of normal luminal architecture were present.

Magnetic resonance imaging (MRI) is also helpful in the evaluation of CNS vasculitis. MRI abnormalities were observed in 90% or more of affected cases, the most common of which were subcortical white matter lesions followed by deep gray matter, deep white matter, and cerebral cortical lesions [23]. Cerebrospinal fluid studies have demonstrated one or more abnormal findings in 88% of confirmed cases, most often elevated protein concentration (median, 98mg/dL) and leukocyte pleocytosis (median, 17 cells/ml) or both citing Salvarani and colleagues [12].

Birnbaum and Hellmann [24] proposed changes to the criteria of Calabrese and Mallek [8]. The proposed criterion for “definite” CNS vasculitis was a positive CNS biopsy. Patients classified as “probable” CNS vasculitis should have CNS angiograms showing changes suggesting vasculitis, concordant MRI abnormalities, and CSF findings consistent with CNS vasculitis but without biopsy confirmation.

Further, discriminatory clinical features of PCNSV and RVCS which might help suggest RVCS in patients with high-probability findings on cerebral angiography and a normal CSF, were female sex, acuteness and severity of the headache, focality of neurological deficits at onset, history of provocative vasospastic syndromes, dynamic improvement after three months, and amelioration with non-cytotoxic therapy [24].

Table 1. Characteristics of PCNSV and RCVS¹

	PCNSV	RCVS
Precipitating factor	None	Post-partum onset or onset after exposure to vasoactive substances
Onset	More insidious, progressive course	Acute onset followed by a monophasic course
Headaches	Chronic and progressive	Acute, thunderclap type
CSF findings	Abnormal (leucocytosis and high total protein concentrations)	Normal to near normal
MRI	Abnormal in almost all patients	Normal in 70% of patients
Angiography	Possibly normal, otherwise, diffuse abnormalities are often indistinguishable from RCVS; irregular and asymmetrical arterial stenoses or multiple occlusions are more suggestive of PCNSV; abnormalities might be irreversible	Always abnormal, strings of beads appearance of cerebral arteries; abnormalities reversible within 5-12 weeks
Cerebral biopsy	Vasculitis	No vasculitic changes
Drug treatment	Prednisone with or without cytotoxic agents	Nimodipine

PCNSV=primary CNS vasculitis; RCVS=reversible cerebral vasoconstriction syndrome; CSF=cerebrospinal fluid

SUBSETS OF PRIMARY CNS VASCULITIS

Further evidence of the heterogeneous nature of PCNSV was appreciated in a review of 101 patients seen at the Mayo Clinic over a 21-year period from 1983 to 2003 [12]. Diagnostic criteria similar to those of Calabrese and Mallek [8] were used. Diagnostic histopathological features were transmural vascular inflammation involving leptomeningeal or parenchymal vessels. Angiographic changes indicating a high probability of vasculitis included areas of smooth-wall segmental narrowing or dilatation and occlusions that affected multiple cerebral arteries without the proximal vessel changes of atherosclerosis or other

causes. Those with single vessel abnormalities in multiple arteries or multiple abnormalities in a single artery were excluded from the analysis. Cases with other conditions that might mimic PCNSV, such as hypercoagulability, varicella zoster virus and other infectious vasculitides, were excluded. There were 58 women and 43 men with a median age at diagnosis of 47 years. The diagnosis of PCNSV was ascertained by cerebral angiography in 70 patients and by CNS tissue in 31 patients. The clinical features of the patients are detailed in Table 2. Patients with large-artery involvement, characterized by multiple, large brain lesions on MRI and diffuse stenoses on angiograms, had more severe neurological disease and worse outcomes. Conversely, those with PCNSV that predominantly affected small leptomeningeal and cerebral arteries, characterized by prominent enhancement of lesions or meninges on MRI after intravenous administration of gadolinium, had less disability and a lower risk of mortality. Moreover, three histological patterns were observed, granulomatous (in 58%), lymphocytic (in 28%), and necrotizing (in 14%) of histologically-proven cases. β -amyloid vascular deposits were noted in 8 specimens, all of which showed granulomatous inflammation. Granulomatous changes were also more frequently encountered in older-onset patients, and in those with altered cognition. These histological patterns appeared to identify subsets of disease rather than different stages of the same process since no individual patient had histological evidence of more than one pattern. Underscoring this hypothesis, were findings in seven patients in whom two biopsy specimens were obtained at different times. In four such patients both specimens were positive for vasculitis and each pair of specimens showed the same inflammatory pattern.

In 2011, Salvarani and colleagues [25] extended the previous cohort of PCNSV [12] to include the period 2004 to 2007, yielding a total of 131 cases, to assess the clinical characteristics of similarly defined patients with PCNSV. Several subgroups were identified. Using a modified Rankin scale [26] to assess outcomes, a subgroup with rapidly progressive PCNSV was distinguished. Among 131 consecutive patients in the updated cohort, 11 (8.4%) had a rapidly progressive course resulting in severe disability or death, (Rankin 5 and 6). Such patients had more frequent paraparesis or quadriparesis at presentation, cerebral angiographic evidence of bilateral, large vessel vasculitis, and MRI evidence of cerebral infarctions. The latter lesions were usually multiple and bilateral, involving both cortex and subcortical regions on initial MRI. Of three open CNS tissue biopsies, one each showed granulomatous changes, necrotizing vasculitis, or both. All 11 patients failed to respond to aggressive immunosuppressant therapy, culminating in stroke as the cause of death in eight and fatal aspiration pneumonia in two patients. One patient who was alive at followup had fixed major neurological impairment.

Eight patients (8%) with biopsy positive-cerebral angiography-negative PCNSV were identified from 101 consecutive patients in the original cohort of Salvarani and colleagues [12, 27]. In comparison to 76 patients with cerebral angiography-positive PCNSV, the former more commonly manifested a cognitive disorder, elevated CSF protein level and leukocyte pleocytosis, and enhancement of meningeal or parenchymal lesions on MRI after administration of intravenous gadolinium. All patients responded to treatment and none died. A similar favorable outcome was reported in children with cerebral angiography-negative PCNSV [18].

Eight (26%) of the 101 patients in the same cohort [12, 28] with positive biopsies also had cerebrovascular amyloid deposits (cerebrovascular amyloid angiopathy or CAA). Compared to PCNSV without CAA, such patients (Figure 1) were comparatively older at

diagnosis, predominantly male, had a more acute onset of PCNSV, with greater frequency of cognitive dysfunction, and prominent enhancement of leptomeningeal lesions by brain MRI after intravenous administration of gadolinium. The presence of vascular amyloid in this group raised the suggestion that the deposits may somehow be an inciting factor in the vascular inflammation. Six of the eight patients responded promptly to therapy, similar to the others in the cohort.

Table 2. Clinical features at presentation in PCNSV¹

Characteristics	All Patients (N = 101), n (%)	Patients Diagnosed by Biopsy (n = 31), n (%)	Patients Diagnosed by Angiography (n = 70), n (%)
Headache	64 (63)	16 (52)	48 (69)
Altered cognition	50 (50)	22 (71)	28 (40)
Hemiparesis	44 (44)	6 (19)	38 (54)
Persistent neurological deficit or stroke	40 (40)	8 (26)	32 (46)
Aphasia	28 (28)	11 (36)	17 (24)
Transient ischemic attack	28 (28)	5 (16)	23 (33)
Ataxia	19 (19)	5 (16)	14 (20)
Seizure	16 (16)	2 (7)	14 (20)
Visual symptoms (any kind)	42 (42)	9 (29)	33 (47)
Visual field defect	21 (21)	5 (16)	16 (23)
Diplopia (persistent or transient)	16 (16)	5 (16)	11 (16)
Blurred vision or decreased visual acuity	11 (11)	0 (0)	11 (16)
Monocular visual symptoms or amaurosis fugax	1 (1)	0 (0)	1 (1)
Papilledema	5 (5)	2 (7)	3 (4)
Intracranial hemorrhage	8 (8)	2 (7)	6 (9)
Amnesic syndrome	9 (9)	4 (13)	5 (7)
Paraparesis or quadripareisis	7 (7)	4 (13)	3 (4)
Parkinsonism or extrapyramidal signs	1 (1)	0 (0)	1 (1)
Prominent constitutional symptoms	9 (9)	4 (13)	5 (7)
Fever	9 (9)	4 (13)	5 (7)
Nausea or vomiting	25 (25)	6 (19)	19 (27)
Vertigo or dizziness	9 (9)	3 (10)	6 (9)
Dysarthria	15 (15)	2 (7)	13 (19)
Unilateral numbness	13 (13)	0 (0)	13 (19)

¹Reproduced from Salvarani C, Brown RD, Jr., Calamia KT et al. Primary central nervous system vasculitis: analysis of 101 patients. *Ann Neurol* 2007; 62:442-51 with permission.

The clinical findings, response to therapy, and outcomes of patients with cerebral vascular β -amyloid deposition with and without inflammatory vascular infiltration were evaluated in 2013 by Salvarani and coworkers in 78 consecutive patients with cerebral vascular β -amyloid deposition [29]. Compared to 118 consecutive patients with PCNSV without β -amyloid deposition, the 28 patients with granulomatous vasculitis (A β -related angiitis or ABRA) had similar results of treatment and outcomes, confirming that ABRA represents a distinct subset of PCNSV.

Sixteen patients (12%) with evidence of intracranial hemorrhage at or near the time of diagnosis of PCNSV were identified from 131 consecutive patient with PCNSV [25], and

reanalyzed further by Salvarani and colleagues [30]. Twelve patients had intracerebral hemorrhages, and four were subarachnoid in location. Twelve were diagnosed by findings on cerebral angiography and four by findings on CNS tissue biopsy. Compared to the 115 patients without intracranial hemorrhage, the 16 affected patients were more frequently women, altogether had less alteration of cognition, persistence of the neurological deficit, stroke at presentation, MRI evidence of cerebral infarction, or needed therapy at last followup visit. Among the four patients with evidence of hemorrhage on CNS tissue biopsy, three showed necrotizing histopathologic pattern of vasculitis. None of the patients with intracranial hemorrhage had evidence of lymphoproliferative disorders, in contrast to one-third in the series described by Calabrese and colleagues [20]. These findings indicate that while intracranial hemorrhage does not occur in the majority of patients with early PCNSV, it nonetheless needs to be considered in the differential diagnosis.

Figure 1. Brain MRI and histopathological features of a PCNSV patient with leptomeningeal vasculitis and amyloid angiopathy. A. MRI at onset of symptoms shows prominent leptomeningeal enhancement after intravenous administration of gadolinium. B. Histopathological findings shows destructive vasculitis with well-formed granulomata in leptomeningeal vessels and wall thickening with eosinophilic material (*) (Hematoxylin and eosin stain X100). The right-hand image shows amyloid- β deposits in all vessels (immunoperoxidase stain for β A4 amyloid X100).

Five patients (5%) with spinal cord involvement were identified from 101 consecutive patients with PCNSV [12, 31]. Five others in the cohort had spinal symptoms but no objective findings and were therefore not included in the spinal group [31]. In the five so studied, the median time from onset of symptoms was 26 days that included leg weakness or paralysis, numbness, and urinary incontinence in all patients, in addition to cerebral symptoms. Symptoms of spinal cord involvement developed before cerebral symptoms in one patient, simultaneously in two patients, and after cerebral disease in two others. Spinal cord vasculitis was the only manifestation in one patient preceding symptomatic brain involvement by 10 months. Spinal cord MRI showed enhancement of thoracic lesions after administration of intravenous gadolinium in all five patients. Cerebral angiography performed in four of the patients were normal. CNS tissue biopsy showed necrotizing vasculitis in three patients and

granulomatous histology in two specimens. Although the small number of patients with spinal cord involvement precluded statistical comparison, there were no significant differences in the clinical and laboratory studies other than symptoms of myelopathy, which occurred exclusively in those with thoracic lesions. Notwithstanding, cerebral angiography showed evidence of vasculitis more frequently in those without spinal cord involvement, while the patients with spinal cord involvement had CNS tissue biopsy findings more often consistent with vasculitis perhaps indicating more widespread disease. Overall, four of the five patients responded to therapy that included corticosteroids alone in one, and combined in the others with cytotoxic agents including cyclophosphamide, azathioprine or mycophenolate mofetil for a median duration of 19 months. Four patients recovered with slight or moderate deficits and disability; however, all sustained at least one relapse or recurrence.

Molloy and colleagues [32] described tumor-like mass lesions (ML) in 38 patients with PCNSV including seven patients from the case records of the Cleveland Clinic, and 31 patients of 535 (5.6%) with PCNSV from the English language medical literature. Patients were included only if they presented with a solitary cerebral ML and histological proof of vasculitis; 13 of 45 (29%) cases of amyloid- β related angiitis (ABRA) reported in the literature were included. The commonest symptoms of PCNSV with a ML were headache (74%), focal neurological deficit (64%), diffuse neurological deficit (50%), and seizures (47%), prompted affected patients to present typically one month after onset compared to patients with PCNSV without a ML who typically presented on average 6 months afterward. Neuroimaging, which detected the ML employing MRI in all 24 patients so studied, and by computed tomography (CT) in 29 of 30 patients, showed edema, contrast enhancement, and hemorrhage in association with the ML respectively in 17, 15, and five patients. Cerebrospinal fluid showed an elevation of the protein content and pleocytosis in two-thirds of patients so studied; and cerebral angiography performed in 14 patients, showed mass effect but no suggestion of vasculitis in eight patients, and angiographic evidence of small vessel vasculitis in the other six. The diagnosis of PCNSV was confirmed by CNS tissue in all 38 patients with granulomatous changes in 20 (53%) and lymphocytic vasculitis in 18 (47%); positive staining for amyloid was found in 13 of 38 CNS tissue biopsies (34%), accompanied by granulomatous vasculitis in 10 of 13 (77%). Overall, 26 of 38 (68%) entered remission status defined as regression of the lesion and resolution or stabilization of neurological symptoms. Six patients died during followup, five of whom were ABRA-positive. Moderate or severe residual deficits were noted in three-quarters of patients, occurred more often in those treated with corticosteroids alone as compared with those administered combination therapy with corticosteroids and cyclophosphamide.

A recent study from Mayo Clinic evaluated the clinical findings, response to therapy, and course of patients with PCNSV associated with lymphoma [33]. Ten patients were identified (6 with Hodgkin lymphoma – HL – and 4 with non-HL) and their findings compared with those from 158 patients with PCNSV without lymphoma seen at Mayo Clinic over 29 years. In 7 patients, lymphoma and PCNSV were diagnosed simultaneously, suggesting an immunologic paraneoplastic mechanism. A granulomatous vasculitis was found in all 8 patients with cerebral biopsies, associated with CAA in 2.

Patients with lymphoma had more neurologic disability at last follow-up and their survival was reduced compared to patients without lymphoma, appearing to have a more severe form of vasculitis.

CONCLUSION

Primary CNS vasculitis is a multifaceted disease with diverse clinicopathological subsets. Affected patients with small-artery vasculitis characterized by positive histology, negative cerebral angiography and prominent leptomeningeal enhancement on MRI after intravenous gadolinium administration have a milder disease course and more favorable outcome compared to those with large-artery PCNSV with multiple large-artery stenoses on cerebral angiography and extensive lesions on MRI. Subsets of patients presenting with rapidly progressive PCNSV, solitary ML, association with lymphoma and vascular amyloid deposits have the worst prognosis.

ABSTRACT

The vasculitides are diseases characterized by inflammation of blood vessels and inflammatory leukocytes in vessel walls. There is an increased propensity for ischemic stroke due to the compromise in vessel lumina and distal tissue ischemia, with hemorrhagic stroke and aneurysmal bleeding due to loss of vessel integrity.

INTRODUCTION

The vasculitides are diseases characterized by inflammation of blood vessels and inflammatory leukocytes in their walls. There is an increased propensity for ischemic stroke due to the loss of vascular integrity with stenosis of vessel lumina and distal tissue ischemia; and hemorrhagic stroke and aneurysmal bleeding due to loss of vessel integrity. The 2012 Revised Chapel Hill Consensus Conference (CHCC) [1] nomenclature provides systemic nosology and a categorization of primary and secondary vasculitides. Central nervous system (CNS) involvement and stroke both occur in the single-organ vasculitic (SOV) syndrome primary CNS vasculitis (PCNSV) [2], as well as, due to limited or multiorgan manifestations of primary systemic vasculitides [1].

PRIMARY CNS VASCULITIS

With several proposed diagnostic schemes for PCNSV over the years [3-5], the combination of clinical and histopathological findings derived from cerebral angiography and leptomeningeal and brain biopsy remains the recommended method of definite diagnosis [6]. This approach facilitates the identification of clinicopathologic subtypes with persistent focal deficits and stroke [2] or intracranial hemorrhage [7] from those with reversible cerebral vasoconstriction syndrome (RCVS) [8] that may mimic true vasculitis, but do not require cytotoxic therapy.

Torres and colleagues [9] did not find a significant correlation between brain and leptomeningeal tissue, and the results of cerebrospinal fluid (CSF), neuroimaging, surgical technique, biopsy characteristics, or preoperative immunosuppressive therapy in 9/79 (11%) patients with suspected CNS vasculitis studied between 2005 and 2013. Yet in nearly three-fold (30%) of patients undergoing biopsy, the investigators noted alternative diagnoses of cerebral amyloid angiopathy, encephalitis, demyelination, and lymphoma. Postoperative complications occurred in 16%, 4% of which were serious. The authors concluded that while brain biopsy remains an important diagnostic tool, however further studies are needed to establish the clinical variables associated with a positive yield, as well as the surgical techniques that are most likely to provide diagnostic results with the lowest complication risk.

Historically, Younger and colleagues [3] described four patients with granulomatous angiitis of the brain histopathologically manifesting necrotizing vasculitis of arteries and veins of varying caliber in conjunction with giant cells and epithelioid cells. These authors [3] noted non-focal symptoms of headache and mental change, followed by focal weakness, seizures, and fatal coma in all four patients. Focal weakness with a stroke onset was noted in two (Patient 1 and 3) of the four patients, Patient 1 had onset of lethargy, focal ptosis and hemiparesis had predominant anterior (ACA), middle (MCA), posterior cerebral artery (PCA) and basilar artery involvement at postmortem examination. Patient 3, who presented with hemiparesis, ataxia, and dysarthria, and found to have predominant small leptomeningeal artery and vein involvement. Altogether, 15% of 78 patients overall had focal weakness with stroke onset compared to 42% who presented with focal deficits during the course of the illness.

In the same year, 1988, Calabrese and Mallek [4] described eight patients with classic angiographic or histopathologic features of PCNSV or so called primary angiitis of the CNS (PACNS), and reviewed the literature of 40 literature cases. Patient 2 [9] who presented with the clinical diagnosis of isolated angiitis of the CNS (IACNS) defined by classical angiographic features, had a clinical onset of transient weakness that progressed to fixed hemiparesis, nonfluent aphasia, alexia, and agraphia with later stabilization after combination prednisone and cyclophosphamide therapy.

Birnbaum and colleagues [5] proposed changes to the criteria of Calabrese and Mallek [4] to include a definite diagnosis of PCNSV only after tissue biopsy confirmation, noting strokes or persistent deficits in less than 20% of patients at onset, and with only about 28% of symptoms overall related to large cerebral vessel involvement. Salvarani and co-workers [2] noted that persistent neurological deficit or stroke and headache were the commonest initial symptoms affecting 68% of 101 patients so studied with PCNSV defined by diagnostic criteria similar to those suggested earlier [4]. Cerebral infarction noted on magnetic resonance

imaging (MRI) of the brain in 53% of patients, were multiple in appearances in 85%, bilateral in 83%, and involved the cortex and subcortex in 63%. Overall, their appearance suggested large-artery, branch-artery or small-artery distributions. Intracranial hemorrhage was noted in 8% of patients, and gadolinium enhancement was found in a third of patients, a quarter of whom demonstrated gadolinium enhancement of the meninges.

Figure 1. Primary CNS vasculitis. T₂-weighted MRI of the brain demonstrates left frontal and parieto-occipital lobe areas of infarction. Reproduced with permission from [10].

Figure 2. Primary CNS vasculitis. T₁-weighted MRI of the brain showed left basal ganglia hemorrhage. Reproduced with permission from [10].

Montefort and co-workers [10] described a 57-year-old man with brain-biopsy confirmed PCNSV and a 2-month history of right arm weakness and numbness superimposed on a history of left-sided headache and intermittent visual field loss. Brain MRI showed evidence of cortical infarction across more than one vascular territory with signal changes consistent with hemorrhage in the left basal ganglia and parieto-occipital lobe. There was angiographic evidence of irregular narrowing and aneurysmal dilatation of the left terminal carotid artery that stabilized without new areas of new infarction after treatment with intravenous pulsed cyclophosphamide and corticosteroids followed by azathioprine. The neuroimaging features of this patient are shown in Figures 1 to 4, as well as, in a similarly affected patient in Figures 5 and 6.

Figure 3. Primary CNS vasculitis. T₁-weighted MRI of the brain demonstrates gyral enhancement after intravenous administration of gadolinium before treatment (A), that resolves after immunosuppressant therapy (B). Reproduced with permission from [10].

Figure 4. Primary CNS vasculitis. Cerebral angiography shows a sessile internal carotid artery aneurysm. Reproduced with permission from reference 10.

Figure 5. Primary CNS vasculitis. T₂-weighted MRI of the brain shows bilateral cerebellar hemispheric infarcts and abnormal signal hyperintensities before treatment (A) that resolve after immunosuppressant.

Figure 6. Primary CNS vasculitis. Cerebral angiography shows widespread vessel irregularity and beading.

PRIMARY LARGE VESSEL VASCULITIS

Giant cell arteritis (GCA) and Takayasu arteritis (TAK) are prototypical large vessel granulomatous vasculitides (LVV). They involve the aorta and its major branches however any size artery can be affected [1]. Imaging studies and fluorescein angiography studies have shown that ocular involvement in GCA can affect not only ophthalmic, but also medium caliber retinal arteries and multiple ciliary arteries and their smaller branches; blindness may result from not only LVV but also injury to smaller ophthalmic branches [1]. Whereas GCA has a predilection for branches of the carotid and vertebral arteries and an age of onset older than 50 years, there is often polymyalgia rheumatic. TAK involves proximal subclavian and carotid arteries with an onset of 40 years or less. Neuroimaging studies employing ultrasonography, high-resolution MRI, and ¹⁸fluorodeoxyglucose-positron emission tomography (FDG-PET) imaging are useful modalities to depict superficial cranial and extracranial vessels, and large vessel subclavian and aortic involvement in GCA and TAK [11].

CNS involvement in GCA, which results from thrombosis of the carotid and vertebral arteries rather intracranial arteritis, affects vessels that contain elastin, more specifically the internal elastic lamina that is absent from intracranial vessels more than 5 millimeters beyond the point of dural perforation. Reich, colleagues [12], Gonzalez-Gay, and co-workers [13] summarized the literature pertaining to stroke and GCA. Reports of CNS involvement have erroneously attributed to intracranial GCA rather than PCNSV [14-16]. Hellenhorset and colleagues [17] noted CNS events including stroke in 7.4% of 175 patients with confirmed GCA, as well as, and one patient with massive cerebral hemorrhage, two with stroke, and six with occlusive disease of the aortic arch. Caselli and colleagues [18] noted transient ischemic attacks or stroke in 7% of 166 patients with biopsy-proven GCA, among whom four had events in the vertebrobasilar systemic, and eight affected the carotid arterial system. With approximately 30% of patients manifesting neurological findings, the commonest of which were neuropathies of the arms and legs according to Caselli and colleagues [18], Salvarani and colleagues [19] observed that transient ischemic attacks or stroke in the territory of the carotid or vertebrobasilar arteries were less common neurological findings.

Gonzalez-Gay and co-workers [13] ascertained the frequency of cerebrovascular accidents (CVA) in association with GCA among 239 patients in a multicenter retrospective analysis to assess the features, therapeutic response, and predictors of visual loss and CVA. Eight patients (3%) developed CVA, equally divided between the vertebrobasilar and carotid territories. Symptoms of vascular ischemia preceded onset of arteritis by a median of 1.5 months, and were more frequent in those with visual involvement, especially permanent visual loss. Two patients with vertebrobasilar stroke died within one month despite aggressive corticosteroid therapy. Stepwise logistical regression analysis revealed visual loss and jaw claudication as the predictors of CVA.

Kerr and colleagues [20] summarized the clinical, laboratory and treatment responses of 60 patients with TAK based upon the presence of symptoms and signs of ischemic, inflammatory large-vessel disease as well as supportive arteriographic findings, noting ten (17%) patients with either transient ischemic attacks or CVA, and carotid or vertebral artery disease, eight of whom corresponded to the neurological deficit. One of the remaining two had hypertension, whereas the other patient had isolated stenosis of the innominate artery.

Riehl [21], and Riehl and Brown [22] reported the clinical and pathological features of six patients with TAK noting widespread arteritis that not only involved the aortic arch and its tributaries by clinical and angiographic studies, but many other medium-, and large-sizes vessels. One patient with TAK manifested clinical and histopathological evidence of CNS involvement. That patient, a 43-year-old woman who presented with rapidly disappearing blood pressure and complained of spells of progressively worsening dizziness and dimness of vision, died of severe congestive heart failure. At postmortem examination, there was severe stenosis of the distal aorta, thrombosis of an aortic arch graft with nearly complete obstruction of all the great vessels by granulomatous panarteritis, as well as vasculitic involvement of the proximal portion of the left MCA, both PCA arteries, and anterior third of the basilar artery. There was massive infarction of the left temporoparietal region, the left half of the midbrain, brain stem, and cerebellum.

PRIMARY MEDIUM VESSEL VASCULITIS

Polyarteritis nodosa (PAN) and Kawasaki disease (KD) are prototypical medium vessel vasculitides (MVV). Although any size of artery is affected in this category, PAN is associated with necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules; however, it is not associated with anti-neutrophilic cytoplasmic antibodies (ANCA) [1]. By contrast, KD is an infantile or childhood disorder that is associated with the mucocutaneous lymph node syndrome, predominantly affecting medium and small arteries, occasionally coronary, the aorta, and other large arteries [1].

Among early postmortem series of PAN, Middleton and McCarter [23] noted CNS involvement due to arteritic lesions in one (Patient 1) that consisted of an occasional small artery. Brain tissue was not examined in one patient (Patient 2) and was not mentioned in another (Patient 3). Kernohan and Woltman [24] summarized the clinicopathological aspects of adult PAN in six patients studied at postmortem examination, estimating CNS involvement associated with stroke in about 8% of cases, and a combination of acute and chronic lesions that correlated with known exacerbations. In three patients, the peripheral nervous system (PNS) was widely involved at onset and at postmortem examination in addition to systemic involvement typically sparing the CNS, while in one patient, the PNS and CNS was involved alone. That patient was a 32-year-old man with onset of left arm and leg hemisensory loss and headache that progressed to paralysis. At postmortem examination, there was marked thickening and near complete obliteration of the right MCA, less so on the left side, and obstruction of the right PCA by a recent thrombus, with a normal PCA on the left. Microscopic analysis showed subacute and chronic lesions of PAN.

According to Guillevin and co-workers [25], CNS involvement is rare but motor deficiencies, stroke and brain hemorrhages can occur as well as cognitive disturbances associated with abrupt memory loss and scattered T₂-weighted hyperintensities on brain MRI suggestive of cerebral vasculitis. CNS involvement including stroke was noted in 9.6% of 115 patients in the FVSG [26] with hepatitis B virus (HBV)-PAN between 1972 and 2002. The FVSG treatment protocol for HBV-PAN generally included cyclophosphamide, corticosteroids and plasma exchange (PE), alone or together, followed by vidarabine,

interferon-alpha (INF- α), or lamivudine, depending upon the time of diagnosis and different treatment protocols available [27-29]. So treated, nine patients (9.7%) who achieved remission subsequently relapsed, one of whom died of stroke, although the relationship between PAN and stroke was not clearly established. A retrospective study of 348 adult patients registered in the FVSG [30] who satisfied criteria for the diagnosis of PAN between 1963 and 2005 noted CNS involvement including stroke in 4.6% of patients overall, with a relatively equivalent frequency among patients with and without HBV-related illness.

PRIMARY SMALL VESSEL VASCULITIS

Small vessel vasculitis affects intraparenchymal arteries, arterioles, capillaries, and venules, however medium-sized vessels and veins are also be involved [1]. Two major categories of SVV include ANCA-associated vasculitis (AAV) characterized by necrotizing vasculitis with few or no immune complex (IC) deposits predominantly affecting small arteries, arterioles, capillaries, and venules associated with myeloperoxidase (MPO) ANCA or proteinase 3 (PR3). Marked vessel wall deposits of immunoglobulin (Ig) and complement characterize immune complex vasculitides. Granulomatosis with polyangiitis (GPA) (Wegener granulomatosis [WG] type), eosinophilic granulomatosis with polyangiitis (EGPA) [Churg-Strauss syndrome [CSS]], and microscopic polyangiitis (MPA) (microscopic polyarteritis) are prototypical AAV, while cryoglobulinemic vasculitis (CV), IgA vasculitis/Henoch-Schönlein purpura (IgAV/HSP), and hypocomplementemia urticarial vasculitis (HUV) associated with C1q antibodies comprise the IC vasculitides; HSP/IgAV is predominantly a disorder of childhood.

ANCA-ASSOCIATED VASCULITIS

Granulomatosis with Polyangiitis

GPA leads to necrotizing granulomatous inflammation of the upper and lower respiratory tracts associated with necrotizing vasculitis of small to medium arteries, arterioles, capillaries, veins, and venules together with glomerulonephritis [1]. Drachman [31] described a patient with one month of headache that awakened him from sleep followed by rhinitis, nasal obstruction, epistaxis, mononeuropathy multiplex, confusion and hypertension. Active arteritis and necrotizing granulomata were found in the brain but not in peripheral nerves. Based upon the observations in a single postmortem studied patient, cerebral involvement according to Drachman [31], depended upon a combination of four separate entities, 1) Frank vasculitis of larger arterial branches particularly over the surface of the brain as demonstrated in his patient report; 2) Ischemia in portions of the territory supplied by the affected vessels; 3) Subarachnoid hemorrhage and hypertensive encephalopathy evidenced by microscopic infarcts in close relation to arteries with fibrinoid impregnation of their walls; and 4) Meningeal infiltration by mononuclear cells. Nishino and colleagues [32] described neurological involvement in 34% of 324 consecutive patients with GPA at the Mayo Clinic between 1973 and 1991 classified according to the American College of Rheumatology

(ACR) [33] that included peripheral neuropathy in 16% compared to cerebrovascular events in 4% at some time in the course of illness, however rarely if ever at presentation. Of five patients with presumed clinical vasculitis, cerebral angiography was negative in two. Of twelve patients studied at postmortem examination, findings of vasculitis were found in only two. Fauci and colleagues [34] noted nervous system involvement in 22% of 85 patients, 10 patients (12%) of whom had CNS involvement including strokes at some point in the illness although not specifically mentioned at presentation. Moore and co-workers [35] estimated the frequency of neurological abnormalities of GPA at 23% to 50%, citing possible mechanisms of neural dysfunction due to inflammation from primary sites, remote granuloma formation, and vasculitis. Drachman [31] opinioned that contiguous extension of necrotizing granulomas might account for 24% of all neurological complications including those of the CNS.

Extensive cerebral infarction in the territory of the bilateral ACA was ascertained in a 67-year-old man with frontal headache that preceded detection of a large midline frontal mass lesion on computed tomography (CT), and known biopsy-proven GPA and granulomatous vasculitis of the nasal cavity, liver and kidney. Postmortem examination showed cerebral infarction in the areas supplied by A2 branches of both ACA, with occlusion of large sized ACA vessels by organized mural thrombi, and fibrinoid necrosis in the arterial branches. There was similar vasculitis with multinucleated giant cells involving small arteries and veins diffusely in the frontal region of the brain suggesting contiguous spread from granulomatous nasal cavity lesions. Hoffman and colleagues [36] retrospectively assessed 180 patients with GPA for 6 months to 24 years noting nervous system involvement in 23% of patients, including CNS involvement and stroke in 8% of patients. A prospective analysis of clinical, electrophysiologic, radiologic, and serologic data of 128 GPA patients over 19 months [37] noted CNS involvement in 7%, the latter including granulomatous infiltration of frontobasal cortex arising from adjacent paranasal sinus granulomas, cerebral vasculitis, stroke, vascular myelopathy, and meningeal granulomatosis.

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing AAV vasculitis with few or no IC deposits and commonly associated glomerulonephritis without granulomatous inflammation [1]. Davson and colleagues [38] separated fourteen postmortem studied patients from 1934 to 1947 with MPA into two groups based upon the presence of severe widespread glomerular damage. Wainwright and Davson [39] described MPA among six post-mortem studied patients from 1947 to 1948, mentioned CNS involvement. However, neither paper [38, 39] recorded stroke or histopathologic evidence of brain involvement. Nor was there mention of patients with CNS involvement by Adu and co-workers [40] among 43 patients with renal histologic evidence of MPA. Savage and co-workers [41], who studied 34 patients with MPA, all of whom presented with clinical evidence of a systemic SVV predominantly affecting the skin and musculoskeletal system associated with focal necrotizing glomerulonephritis, cited CNS involvement at presentation in 18% of patients without specific mention of stroke. Serra and colleagues [42], who reported the presentation, histopathology and long-term outcome of 53 patients with MPO from 1965 to 1981, cited CNS involvement at presentation in 15% of patients, the findings of which included stroke, convulsions, headache, confusion and

drowsiness. Guillevin and co-workers [43] who reported the clinical and laboratory findings in 85 patients from the FVSG with MPA from 1969 to 1995, noted CNS involvement in 11.8% of patients at presentation and in 3% of 29 patients who experienced a relapse; however, there was no specific mention of stroke. Gayraud and co-workers [44] analyzed four prospective trials that included 278 patients with PAN, MPA and EGPA from 1980 to 1993, that reported stroke occurrence that accounted for 85 deaths. Villiger and Guillevin [45], who reviewed several retrospective European patient cohorts [40-43, 46], cited CNS involvement that included subarachnoid hemorrhage, cerebrovascular disease, meningitis and diffuse brain injury. Ben Sassi and colleagues [47] described intracerebral hemorrhage secondary to necrotizing vasculitis that similarly involved the nerves and muscles, citing three additional patients with hemorrhagic stroke due to MPA [48-50]. Ahn and colleagues [51] studied 55 patients with MPA, 69% of whom demonstrated perinuclear ANCA by immunofluorescence (IF) or MPO ANCA-seropositivity, noting CNS involvement in 5 (9.1%), none of whom developed end-stage renal disease. and one of whom died at follow-up without known autopsy.

Eosinophilic Granulomatosis with Polyangiitis

EGPA is a necrotizing vasculitis involving small to medium vessels that differs from GPA by the presence of eosinophil-rich necrotizing granulomatous inflammation of the respiratory tract in association with asthma and eosinophilia, and ANCA seropositivity when glomerulonephritis is present [1]. Churg and Strauss [52] described the clinical and postmortem findings of thirteen patients with asthma, fever, and hypereosinophilia. This was accompanied by eosinophilic exudation, fibrinoid change, and granulomatous proliferation that constituted the so called allergic granuloma. The latter were found within vessels walls and extravascular connective tissue of major organ systems. CNS organ manifestations were described in 8 (61.5%) of patients, and the cause of death in 3 patients who sustained cerebral hemorrhage or subarachnoid hemorrhage. Chumbley and co-workers [53] described 30 asthmatic patients from the Mayo Clinic over the period from 1950 to 1974 with necrotizing vasculitis of small arteries and veins, extravascular granulomas and infiltration of vessels and perivascular tissue eosinophilia. Lanham and colleagues [54], who emphasized that the combination of necrotizing vasculitis, tissue infiltration by eosinophils and extravascular granulomas suggested by Churg and Strauss [52] occurred contemporaneously in only a minority of patients, and that such histological findings could be encountered in other granulomatous, vasculitic and eosinophilic disorders in the absence of clinical asthma, allergic rhinitis, sinusitis, pulmonary infiltrates, and cardiac involvement pathognomonic of EGPA, noted CNS involvement in 25% of cases. Cerebral hemorrhage and infarction as a consequence of vasculitis or hypertension was a major cause of morbidity and mortality, accounting for 16% of deaths.

Sehgal and colleagues [55] noted neurological involvement among 14 patients with the clinical diagnosis of EGPA, three of whom had cerebral infarction two to fifteen years after initial diagnosis. The first patient was a 68-year-old woman with a stroke involving the territory of the MCA manifested as hemiparesis and aphasia. The second patient was a 34-year-old man with a right parietal lobe infarction pursuant to embolization of a left ventricular

thrombus, manifested incoordination and hemisensory loss of the arm. The third patient was a 62-year-old woman with a thalamic infarction who manifested hemibody sensory loss. Guillemin and co-workers [56] studied 96 patients with EGPA between 1963 and 1995, noting ischemic stroke onset in 6 (6%) by brain computed tomography (CT). Mouthon and colleagues [57], reported 38 patients with EGPA from 1978 to 1998, citing CNS involvement in 3 elderly patients (7.9%) in whom CNS vasculitis was suggested by MRI of the brain in only one patient. Among 383 patients with EGPA enrolled in the FVSG Cohort [58] employing the definition of the ACR [59], CNS involvement was noted in 20 (5.2%) of patients at onset, with two-fold greater frequency of ANCA-seropositive serology than those ANCA-seronegative, but no specific mention of stroke frequency.

IMMUNE COMPLEX VASCULITIS

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis (CV) or CryoVas is typified by cryoglobulinemic IC deposited along small vessels predominantly arterioles, capillaries, veins, and venules in association with serum cryoglobulins. In mixed cryoglobulinemia (MC), the immune complex is composed of IgM and polyclonal IgG with rheumatoid factor activity often in association with hepatitis C virus (HCV) infection. Disease manifestations of cryoglobulinemia was noted in 206 of 443 (47%) patients [60] that included palpable purpura, 12 (6%) of whom had CNS involvement; HCV Infection was the main etiologic factor noted overall in 75% of the 443 patients. A concomitant autoimmune disorder was noted in 24%, hematologic disease in 7%, and essential cryoglobulinemia in 11% of the patients overall. The original patient described by Lerner [61], a 56-year-old man who presented with chest pain, purpuric rash and a cold precipitating serum protein, did not have symptoms or postmortem findings referable to the nervous system. Marshall [62] noted widespread cerebral purpura with hemorrhage ascribed to occlusion of small blood vessels by eosinophilic protein precipitates that correlated with the clinical presentation of progressively fatal coma.

Abramsky and Slavin [63] described three patients with MC and CNS involvement. The first was a 55-year-old woman with anarthria, hyperreflexia, bilateral Babinski signs and progressively fatal coma, who was later found at postmortem to have multiple thrombotic occlusions of small intracerebral blood vessels with adjacent foci of ischemia and marked demyelination. The second patient was a 50-year-old woman, who presented with a Wallenberg syndrome and was found to have MC with occlusion of the left posterior inferior artery at angiography. The third patient, a 50-year-old woman who presented with right hemiparesis and pyramidal signs, was found to have a cryoprecipitate and occlusion of the left MCA.

Gorevic and colleagues [64] summarized the clinical aspects of long-term followup of 40 patients with MC noting incidental CNS involvement at postmortem examination and a fatal stroke in another patient. Petty and co-workers [65] described a 35-year-old woman with type II cryoglobulinemia, headache, purpura, and seizures who was found to have multiple areas of T₂ and proton density signal abnormalities in the cerebral and cerebellar hemispheres, with a

gyral pattern of enhancement in the cerebral cortex, a nodular pattern of enhancement in the cerebellum, and early cortical infarction on right frontal brain biopsy without vasculitis; cerebral angiography was normal. HCV RNA was detected by polymerase chain reaction (PCR). Ince and colleagues [66] described a patient with paranoid psychosis and MC who was found to have right basal ganglia hemorrhage and multifocal small vessel occlusions by amorphous bland protein plugs and abundant Russell bodies present in arterioles and venules with relative sparing of capillaries.

Stroke was the presenting feature of CNS involvement in MC among two patients with lacunar infarcts and associated subcortical white matter changes on brain MRI [67, 68], and in one patient with a temporal arteritis-like syndrome with associated ischemic cerebral infarction [69]. Cacoub and co-workers [70] compared the features of patients with HCV examined for systemic vasculitis manifestations of PAN or MC noting two patients with cerebral vasculitis in the former versus none in the latter. Cacoub and colleagues [68] described CNS involvement in three patients with HCV infection and MC, one of whom was found to have a hemorrhagic lesion of the external capsule in association with pontine T₂ hyperintensities and parietal lobe infarcts. A second patient had a hemorrhagic occipital lobe lesion in association with cerebellar infarction and abnormal periventricular hyperintensities. A third patient had abnormal white matter hyperintensities.

Ferri and colleagues [71] studied the demographic, clinical, serologic features and survival of 231 patients with MC seen between 1972 and 2001, noting widespread vasculitis involving small- to medium-sized arteries, capillaries and venules with two or more visceral organs including the kidney, gut, and lung, noting no CNS manifestations of MC with exception of focal dystonia during interferon treatment in one patient [71]. Filipini and colleagues [72] reported a 63-year-old woman with acute severe encephalopathy HCV-related MC, dysarthria and hemiplegia. Fragoso and co-workers [73] reported a 35-year-old woman with dysarthria, left facial and left limb hemiparesis and hemisensory loss with MC in whom MRI showed ischemic lesions in the tail of the right caudate nucleus, corona radiata and posteromedial putamen. Casato and co-workers [74] reported the CNS findings in 40 patients with HCV-related CV in a multicenter, case-control study using MRI and neuropsychological testing. Although none evidenced cerebral infarction, small white matter lesions were found in all HCV-related MC subjects, a higher mean number of white matter intensities compared to HCV and healthy controls.

Terrier and co-workers [75] analyzed the data of 242 patients registered in the CryoVas survey ascertaining CNS involvement in 5 (2%) patients without specifying whether stroke was encountered. Terrier and Cacoub [76] reviewed CNS findings in HCV-seronegative and seropositive MC in CryoVas noting 2 (0.7%) patients among the former with CNS involvement, compared to 9 (5%) patients in the latter group evidencing CNS involvement but without further mention as to presence of stroke in any of the patients.

Hypocomplementemic Urticarial Vasculitis/C1q

Hypocomplementemic urticarial vasculitis/C1q presents with recurrent attacks of erythematous, urticarial and hemorrhagic skin lesions lasting up to 24 hours at a time, associated with recurrent attacks of fever, joint swelling, and variable abdominal distress.

Circulating hypocomplementemia and C1q antibodies are associated with necrotizing SVV in skin biopsy tissue affecting arterioles, capillaries, and venules [1]. Apart from orbital pseudotumor with ptosis, diplopia, and headache in one patient with HUV syndrome, there was no mention of CNS involvement or stroke in a review of 18 patients with HUV/C1q [77]. Nor was stroke mentioned in a review of four patients studied at postmortem examination with HUV/C1q [78]. Buck and colleagues [79] cited rare CNS manifestations in HUV/C1q including aseptic meningitis, pseudotumor cerebri, transverse myelitis but no mention of stroke or cerebral vasculitis. Grotz and colleagues [80] did not mention stroke or CNS vasculitis in a case report and review of the literature of HUV/C1q. In a review of HUV/C1q, Davies and Brewer [81] cited CNS involvement as “very rare”, attributing development of pseudotumor cerebri to vasculitis of the venous sinus system. Ludivico and colleagues [82] suggested that chronic pseudotumor cerebri in their patients was a diagnosis of exclusion and possibly related to chronic corticosteroid use, but did not cite patients with cerebral vasculitis or stroke.

Chapter 221

CENTRAL NERVOUS SYSTEM VASCULITIS DUE TO INFECTION

David S. Younger^{1,*}, MD, MPH, MS and Patricia K. Coyle², MD

ABSTRACT

A number of pathogens have the propensity to involve blood vessels during central nervous system infection which can lead to cerebrovascular complications. Infection is a recognized cause of secondary central nervous system vasculitis. It is very important not to miss the diagnosis of infection-related central nervous system vasculitis since specific antimicrobial therapy may be necessary; this chapter reviews the major implicated organisms.

INTRODUCTION

Vasculitis or angitis is defined as inflammation of blood vessels. Vasculitic involvement of large, medium and small caliber vessels respectively leads to arteritis, venulitis and capillaritis alone or in combination. Central nervous system (CNS) vasculitis typically affects blood vessels within the brain and rarely the spinal cord. It can also lead to a range of complications including ischemic infarction, intracerebral or subarachnoid hemorrhage,

* Corresponding Author's Emails: david.younger@nyumc.org; <http://www.davidyounger.com>.

mycotic aneurysms, venous thrombosis, and transient ischemic attacks (TIA). Three suggestive clinical patterns are shown in Table 1 [1].

Table 1. Suggestive clinical presentations for CNS vasculitis*

● Encephalopathy with headache ● Intracranial mass lesion with headache and other abnormalities ● Atypical relapsing multiple sclerosis picture (with headache, seizures, encephalopathy, stroke-like features)

*Adapted from reference [1].

Infection is a recognized cause of secondary CNS vasculitis. In a series of 16 patients with CNS vasculitis not due to primary CNS angiitis, 12.5% of cases were attributed to infection [2]. The 2012 Revised Chapel Hill Consensus Conference (CHCC) Nomenclature considered infectious vasculitis as vasculitis associated with a probable etiology [3]. Infection can injure blood vessels in different ways. The pathogen may bind to or actually infect endothelium, or may trigger an adjacent immune or toxic response that indirectly affects vasculature. Blood vessel injury may reflect the sequela of direct infection, compressive inflammatory exudate, septic emboli, or formation of mycotic aneurysms. The infectious agents associated with CNS blood vessel disease are shown in Table 2.

BACTERIAL PATHOGENS

Acute Septic Meningitis

Acute septic bacterial meningitis is associated with vascular complications in 15% to 20% of patients [4]. Vascular complications typically occur early including days to weeks following initiation of antibiotic therapy. Invasive pneumococcal disease (IPD) is defined as a proven isolation of *Streptococcus (S.) pneumoniae* bacteria from normally sterile sites such as blood or cerebrospinal fluid. It remains a major cause of morbidity and mortality worldwide despite the availability of antibiotic therapy and vaccines. Host as well as bacterial factors contribute to IPD pathogenicity. Ethnicity, extremes of age, comorbidities and alcoholism are well-known host risk factors associated with increased susceptibility and higher mortality. Pneumococcal meningitis remains a potentially devastating disease with high mortality rate and neurological damage among those who survive. Focal neurological findings may be present during the acute phase of bacterial meningitis, but more often occur after a few days as immunological complication of meningitis. Case death rates and risk of sequelae following meningitis are higher for *S. pneumoniae* than *Neisseria meningitidis* or *Haemophilus influenza* infection.

The ensuing proinflammatory cascade triggered by *S. pneumoniae* and self-perpetuated by a dysregulated host inflammatory response, triggers mediators with vascular toxicity resulting in seizures, diffuse brain swelling, hydrocephalus, hearing loss and ischemic or hemorrhagic stroke. Arteries are involved more often than veins, and show narrowing on ultrasonography [5]. Ischemic complications result from vasculitis, vasospasm, associated endocarditis, or intra-arterial thrombosis [5].

Among 87 consecutive adult patients with pneumococcal meningitis, mortality was 24.1% [6]. Cerebrovascular arterial complications were seen in 21.8%, and venous complications in 10.3% of cases. Bacterial meningitis produces a subarachnoid inflammatory exudate that worsens over time, encasing large vessels at the base of the brain. Invasion of blood vessel walls by inflammatory cells leads to edema, focal stenosis and dilation, and intimal thickening. Large and medium vessels are typically involved in the Circle of Willis and along the terminal internal carotid artery (ICA), but the process can spread to involve smaller vessels as well. While vasculitis and vasospasm lead to cerebral ischemia and infarction however, disseminated intravascular coagulation may also supervene in the setting of septic meningitis and hypercoagulability, with activation of antifibrinolytic, proinflammatory, and procoagulant pathways. Pneumococcal meningitis was associated with cerebral venous thrombosis and carotid and vertebral artery dissection in one reported patient [7]. There are reports of late stroke with pneumococcal meningitis involving small penetrating arterioles [8].

Table 2. Infectious agents associated with CNS blood vessel disease

Bacterial Pathogens: ● Agents of Acute Septic Meningitis: <i>S. pneumoniae</i>, <i>N. meningitidis</i>, etc. ● Infective Endocarditis ● <i>Mycobacterium tuberculosis</i> ● Spirochetal Infections: <i>T. pallidum</i>, <i>B. burgdorferi</i>, and <i>Leptospiriosis</i> ● <i>Mycoplasma pneumonia</i> ● <i>Bartonella</i> ● <i>Tropheryma whippelii</i>
Viral Pathogens: ● Herpes Pathogens: VZV, CMV, HSV 1 and 2; EBV ● Retroviruses (HIV, HTLV-1) ● Hepatitis Agents: HBV, HCV ● Parvovirus B19 ● West Nile Virus ● Rare cases: Adenovirus, Echo/Coxsackie, Parainfluenza, Rubella
Fungal Pathogens: ● <i>Aspergillus</i> ● <i>Candida</i> ● <i>Coccidioides</i> ● <i>Cryptococcus</i> ● <i>Exserohilum rostratum</i> ● <i>Histoplasma capsulatum</i> ● <i>Mucormycosis</i>
Parasitic Pathogens: ● <i>Taenia solium</i> (Neurocysticercosis) ● <i>Plasmodium falciparum</i> (Malaria) ● <i>Schistosoma mansoni</i> ● <i>Toxoplasma gondii</i>
Rickettsial Pathogens: ● <i>Rickettsia rickettsiae</i> (RMSF) ● Scrub typhus

Abbreviations: VZV, Varicella zoster virus; CMV, cytomegalovirus; HSV, herpes simplex virus; EBV, Epstein Barr virus; HIV, human immunodeficiency virus; HTLV-1, human lymphotropic virus type 1; HBV, hepatitis B virus; HCV, hepatitis C virus; RMSF, Rocky Mountain Spotted Fever.

There can be delayed or chronic vasculopathy and progressive arterial stenosis consistent with late immune-mediated mechanisms, the hypercoagulable state, or rebound inflammatory effects [4, 8, 9]. Such patients are exceptional but may respond to corticosteroid therapy.

Infective Endocarditis

Infection of the endocardial inner lining of the heart can involve heart valves, mural endocardium, and septal defects [10]; valvular heart disease is a predisposing factor for infective endocarditis. The commonest site of valvular infection is the mitral followed by the aortic valve; the pulmonic valve is the least frequently involved. Mitral valve carries the highest risk for CNS emboli as noted in Table 2. Both sterile and infected emboli may occur as a result of endocarditis. CNS vasculitis is a concern in the setting of subacute rather than acute endocarditis. Both isolated angiitis of the central nervous system (IAN) and bacterial endocarditis may present with similar clinical and auxiliary findings.

Endocarditis is generally due to bacterial infection, although fungi, *Rickettsiae* and viruses are occasional agents [11]. The microorganisms most commonly implicated are *Staphylococcus (S.) aureus*, followed by *Streptococcus viridans*, coagulase-negative *Staphylococci*, other streptococci, and gram negative rod organisms [12]; *S. aureus* in particular infects endothelial cells. *Streptococcus bovis* is a rare cause of infective endocarditis in association with occult gastrointestinal tumors in up to 56% of cases [10]. Bacteremia associated with gingivitis due to *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella* and *Kingella* (HACEK) organism with pneumonia or pyelonephritis, can infect sterile fibrin-platelet vegetation. Infection occurs with trivial everyday activities such as brushing of teeth, bowel movements, and invasive procedures such as dental extraction, prostate removal, endoscopy or colonoscopy, barium enema, and trans-esophageal echocardiography. Intravenous (IV) drug use is a risk factor for infectious-related endocarditis. Indwelling lines can be a source of bacteremia. Internal jugular lines are more likely to become infected than subclavian lines. Subacute endocarditis is not only associated with embolism, but it promotes the formation circulating immune complexes, cryoglobulins, agglutinating and complement-fixing bactericidal antibodies.

CNS complications occur in 20% to 40% of patients with infective endocarditis, the commonest of which is stroke due to septic embolism [11, 13, 14]. Clinically diagnosed intracranial mycotic aneurysms complicate 2% to 3% of infective endocarditis cases, although the postmortem rate is in the range of 5% to 10%. About 2% to 6% of all intracranial aneurysms are due to infection, tending to affect distal portions of secondary and tertiary branches of the middle cerebral artery (MCA).

The clinical features of neurologic involvement in endocarditis may initially be very subtle with nonspecific fever; headache, fatigue, and malaise are common. Abnormalities on physical examination suggestive of embolism include Janeway lesions, splinter hemorrhages, and Roth spots; multiple ischemic strokes may also be present. Rupture of resultant mycotic aneurysm can lead to acute catastrophic hemorrhage, the symptoms of which depend upon the location. Multiple microscopic emboli can lead to non-focal encephalopathy.

A recent analysis of neurologically asymptomatic patients with infective endocarditis [13] found that 71.5% of cases manifested occult brain magnetic resonance imaging (MRI)

abnormalities consisting mainly of multiple small infarcts in a watershed distribution, and cerebral microscopic hemorrhages within cortical regions.

Most affected patients demonstrate leukocytosis, elevated acute phase reactants, and positive blood cultures. Diffusion-weighted and gradient-echo MRI sequences are recommended to image the commonest findings in affected patients that include ischemia and hemorrhage. While brain computed tomographic angiography (CTA) and MR angiography (MRA) detect mycotic aneurysms measuring 3 mm to 4 mm or larger in size, digital subtraction angiography (DSA) remains the gold standard, but can be associated with serious complications.

The differentiation of infective endocarditis and primary cerebral vasculitis is extremely important [15]. Therapy of infective endocarditis includes both supportive care and medical interventions whereas cerebral vasculitis requires immunosuppression. Failure to accurately distinguish the two can result treatment failures and heightened morbidity and mortality. A comparison of the findings of six patients with biopsy-proven CNS vasculitis with the data of six patients with infective endocarditis showed that the former were generally younger (27-62 years) and presented with multiple strokes ($n = 4$), intracerebral hemorrhage ($n = 1$), epileptic seizures ($n = 2$), or encephalopathy ($n = 1$). All had pathologic cerebrospinal fluid (CSF) findings including pleocytosis ($n = 5$), protein elevation ($n = 4$), and angiography revealed multilobar stenoses in two cases while digital subtraction angiography was normal in four. Those with infective endocarditis were generally older (32-77 years) and presented with multiple ($n = 3$) or single ischemic strokes ($n = 2$) or encephalopathy and headache ($n = 2$). While all patients showed inflammatory serum findings (C-reactive protein $n = 6$, leukocytosis $n = 4$), CSF-pleocytosis was present in two cases only. Angiography revealed a vasculitic pattern in two patients. The diagnosis of BE was established based on transesophageal echocardiography and blood cultures. Leptomeningeal and brain biopsies performed in two cases were normal. Patients with either cerebral vasculitis or infective endocarditis may present with multiple strokes and encephalopathy. The frequency of a vasculitic pattern in angiography is similar in both conditions. While inflammatory serum findings are the rule in infective endocarditis, pathologic CSF findings were present in all of those with cerebral vasculitis. Transesophageal echocardiography and blood cultures should be performed in order to diagnose or exclude infective endocarditis in those at higher risk. Notwithstanding, immunosuppressive therapy may be dangerous in suspected cases of cerebral vasculitis without a confirmatory brain and leptomeningeal biopsy.

Mycobacteria

Mycobacterium (M.) tuberculosis (TB) meningitis was the first type of meningitis to be described clinically as *dropsy* of the brain in 1768, and subsequently shown to be inflammatory when meningeal tubercles and visceral tubercles were found to be identical in 1830. The tuberculoma, once the commonest intracranial tumor, is now exceptionally rare. The chief neurological signs and symptoms of tuberculous meningitis reflecting meningeal irritation are neck stiffness and positive Kernig sign; and raised intracranial pressure notably headache and vomiting with mental changes, seizures, and focal neurological signs. Arteritis is the rule in the vicinity of tuberculous lesions, wherein vessel walls are invaded by

mononuclear cells, with the adventitia more heavily involved than the media [16]. The subintimal and intimal regions form a layer of homogenous fibrinoid material that later involves the media, and the vessel lumen is reduced by inflammatory cell exudation beneath the fibrinoid material, the end results of which are reduction or complete obliteration of the lumen, proliferative endarteritis, and cerebral infarction. The vessels most heavily involved are those at the base of the brain and others in the Sylvian fissure. CNS involvement, which occurs in only 1% of TB infections, has the greatest mortality of any organ involvement], with fatality or severe residual mortality noted in up to one-half of cases of resultant TB meningitis [17]. Children and human immunodeficiency virus (HIV)-infected individuals are at special risk for developing CNS involvement. Polymorphisms in genes involved in the innate immune response such as the toll-like receptor 2 gene may influence dissemination and development of TB meningitis [17]. The pathogenesis of infection is usually due to rupture of a previously seeded meningeal, subpial, or subependymal focus. Chronic meningitis produces a thick, gelatinous inflammatory exudate that results in intimal thickening with obliterative vasculitis involving vessels at the base of the brain. Stroke occurs in 15% to 60% of affected patients and may be more common in HIV-infected individuals [4, 18]. Cerebral Infarction can be clinically silent, overshadowed by the meningeal features, or insidious in development. TB-related strokes show a predilection for the anterior rather than posterior circulation. The basilar exudates produce inflammatory vascular changes within the Circle of Willis. Distal ICA, proximal MCA and its perforating branches are particularly affected [17]. More severe meningitis carries a greater risk for vascular involvement. Vasospasm impacts strokes in the early period while proliferative intimal disease is a factor in later outcome. The immune reconstitution inflammatory syndrome (IRIS) can supervene during treatment for extraneural TB, unmasking latent TB meningitis and presenting with neurologic features including stroke. Hydrocephalus is a common sequela with often associated meningeal enhancement particularly along basal brain regions. Contrast-enhanced MRA is more sensitive in the detection of small vessel involvement. Pathologically-proven TB-associated CNS vasculitis has been described in five heterogeneous patients to date [16].

The diagnosis is confirmed by detection of TB bacilli in CSF using a Ziehl-Neelsen stain and culture, as well as a positive polymerase chain reaction (PCR). A positive yield is increased with large sample volumes, and ventricular CSF demonstrating an even higher yield than lumbar CSF. Interferon (INF)- γ releasing assays and TB antigen analysis can be studied in CSF [20]. Neuroimaging features of basilar exudate and hydrocephalus are suggestive.

Treatment involves induction therapy for two months with isoniazid, rifampin, pyrazinamide, and a fourth drug either streptomycin or ethambutol, followed by maintenance therapy with two drugs for an additional seven to ten months, typically isoniazid and rifampin. Fluoroquinolones are used in multidrug resistant cases. Adjunctive corticosteroids may be warranted in the first six to eight weeks. Aspirin is potentially useful in reducing stroke and mortality [20].

Spirochetal Agents

Spirochetes, which have a propensity to cause vasculopathy, can be associated with CNS vascular disease.

Syphilis

Syphilis is a spirochetal infection due to *Treponema (T.) pallidum*. Infection is acquired or congenital, with an estimated worldwide annual incidence of 12 million new adult cases [21]. About 4% to 10% of untreated patients develop CNS involvement. Symptomatic neurosyphilis presents with meningitis and meningovascular syndromes. Meningitis occurs in the first year of infection, producing basilar meningitis often culminating in stroke and vasculitis. Meningovascular syphilis comprises 39 to 61% of all symptomatic cases of neurosyphilis. It is characterized by obliterative endarteritis that affects blood vessels of the brain, spinal cord and leptomeninges, precipitating substantial ischemic injury. Often referred to as Heubner arteritis, it involves medium-sized to large arteries with lymphoplasmacytic intimal inflammation and fibrosis however there is a variant form termed Nissl-Alzheimer arteritis that characteristically affects small vessels and produces both adventitial and intimal thickening. Both types can lead to vascular thrombotic occlusions and cerebral infarction, with preferential involvement of the MCA

Meningovascular syphilis occurs months to years later associated with perivascular inflammatory endarteritis that leads to luminal narrowing and rarely dilatation. It typically involves large and medium-sized intracranial vessels, in particular the MCA, as may small intracranial vessels, altogether comprising 15% to 23% of cases [4].

Patients may experience prodromal symptoms of headache, vertigo, insomnia, and behavioral changes. Stroke symptoms developed in a subacute progressive pattern in one-quarter of patients. A recent Australian series [21] noted a prevalence of 4% for stroke or TIA among those with seropositive meningovascular syphilis.

The affected supraclinoid ICA and proximal vessels of the Circle of Willis show smooth or beaded segmental narrowing on neuroimaging, without common or cavernous ICA involvement atypical for atherosclerotic disease. Amorphous proteinaceous firm masses with a necrotic center surrounded by inflammatory tissue termed gumma are noted in the brain of patients with tertiary syphilis and meningovascular disease.

The fluorescent *Treponemal* antibody (FTA-Abs), which detects specific *T. pallidum* antibodies later in the course of the disease, can be used to confirm the results of plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests which register reactivity to cardiolipin-lecithin-cholesterol antigen elaborated early in the course of syphilis exposure. The CSF in affected patients with neurosyphilis demonstrates pleocytosis, reactive VDRL, and increased intrathecal *T. pallidum* antibody index. All patients should be checked for HIV infection. Treatment of neurosyphilis is IV penicillin for 10 to 14 days with CSF monitoring in HIV-positive individuals to document normalization. Aspirin 81mg daily can be added for stroke prophylaxis.

The search for the cause of stroke in young adults should include meningovascular syphilis as a potential etiology. Sudden acute severe headache heralded onset of occlusion of bilateral vertebral and proximal basilar artery documented by MRA was noted in an African man who responded to thrombectomy with restoration of blood flow but succumbed to fatal pontine and subarachnoid hemorrhages [22]. Postmortem examination revealed RPR and a positive VDRL test in CSF with CNS vasculitis characterized by mural thrombi along the vertebrobasilar arteries with well-defined lines of Zahn of alternating layers of fibrin, platelet and red blood cell aggregates, and inflammatory cell infiltration of the arterial walls particularly in the adventitia. Another patient with abrupt onset of confusion, aphasia, and hemiparesis had carotid angiography that documented normal named cerebral vessels except

for smaller than average caliber, with an abnormal complement fixation test of the blood and CSF, positive colloidal gold curve test, and leptomeningeal biopsy that showed lymphocytic infiltration, focal fibrosis, and chronic perivascularitis consistent with meningovascular syphilis [23].

Lyme Neuroborreliosis

The term Lyme neuroborreliosis was introduced by Veenendaal-Hilbers and colleagues [24] in 1988 to emphasize that CNS involvement due to Lyme disease. *Borrelia (B.) burgdorferi sensu lato* is the spirochete responsible for Lyme disease. *B. burgdorferi sensu stricto*, hereafter referred to as *B. burgdorferi*, is the species agent that causes Lyme disease and its neurological complications in North America; *B. garinii* and *afzelii* species predominate outside of North America. Virtually all cases result from an infected *Ixodes* tick bite. Lyme disease is a systemic infection with most patients manifesting the prototypical expanding skin lesion at the bite site termed erythema migrans. Both the CNS and peripheral nervous system (PNS) are targeted body organs. CNS vasculitis while exceedingly uncommon, probably accounted for less than 1% of all Lyme disease cases in endemic area. Patients with Lyme neuroborreliosis may present with cerebral infarction, intracerebral or subarachnoid hemorrhage, and TIA [25-30].

Only three patients reported in the literature with neurovascular clinical syndromes ascribed to CNS vasculitis in which detailed information was available including documentation of positive CSF Lyme serology, were ultimately found to have verifiable vasculitis [28-30]. Two patients [28] presented with headache were ultimately noted to have histopathologically confirmed vasculitis on brain biopsy. Patient 3 of Oksi and colleagues [28] was an 11-year-old boy with headache and hyperactivity syndrome who developed gait difficulty concomitantly with a stroke visualized on brain MRI. Subsequent craniotomy and biopsy of the area of enhancement disclosed lymphocytic vasculitis of small vessels without fibrinoid necrosis, and CSF *B. burgdorferi* serology was positive. Headache and the MRI improved with intravenous antimicrobial therapy. Patient 2 of Topakian and coworkers [29] presented with headache, fatigue, malaise, nausea and vomiting first considered migrainous then psychosomatic until subsequent MRI disclosed ischemic brain infarctions, MRA was compatible with diffuse vasculitis, and CSF showed lymphocytic pleocytosis with positive oligoclonal bands, and diagnostic CSF and serum *B. burgdorferi* serology. Brain biopsy showed vasculitis involving leptomeningeal arteries comprised of lymphoplasmacytic vessel wall infiltration with focal necrosis. Epithelioid cells were beaded in multiple granuloma-like formations in the leptomeninges. There was symptomatic improvement after a course of intravenous antimicrobial therapy. The third patient reported by Miklossy and colleagues [30], a 50-year-old man with leg spasticity and CSF pleocytosis for 15 months who progressed to hemiparesis and ventilatory support, was later found to have diagnostic *B. burgdorferi* serology in serum and CSF. Postmortem examination showed perivascular lymphocytic inflammation of leptomeningeal vessels, some of which displayed infiltration of the vessel walls, duplication of the elastic lamina, narrowing of lumina, and complete obstruction of some leptomeningeal vessels by organized thrombi.

There are rare instances of cerebral venous sinus thrombosis. *B. burgdorferi* infection in the CNS may be associated with lymphocytic cerebral vasculitis [31] preceding clues of which include, headache, arthralgia, myalgia, peripheral facial nerve palsy, and flu-like illness during the summer months. Laboratory evaluation may demonstrate meningeal enhancement

on brain MRI although there appears to be a propensity of vasculitis to involve the posterior circulation. Lumbar CSF analysis typically reveals pleocytosis, increased protein, and intrathecal Lyme antibody production. CNS vasculitis due to Lyme neuroborreliosis should be treated with IV ceftriaxone 2 grams daily for four weeks via midline or permanent intravenous catheter (PIC) line with daily acidophilus to lower risk of *Clostridium difficile* colitis.

Leptospirosis

Leptospirosis is a worldwide zoonotic infection due to a spirochete from the genus *Leptospira*. It is transmitted by the urine of infected animals, and to people exposed to the pathogenic organism through contact with contaminated water, blood or soil. Infection is biphasic, with flu-like symptoms, followed by a second immune phase that can involve meningitis, jaundice with liver injury, and renal failure. Infection can be asymptomatic. About 90% of symptomatic infections manifest a benign biphasic febrile illness with 10% involving icteric Weil disease, and a fatality rate of 10%. Spirochetes are found in blood and CSF early in the course of the illness, and in the urine later in the disease. Leptospirosis more commonly causes meningitis or meningoencephalitis. Clinically apparent CNS vascular involvement is unusual but can result in stroke, hemorrhage and venous sinus thrombosis [32-34]. Diagnostic tests include screening serology via enzyme linked immunosorbant assay (ELISA), microscopic agglutination test, and polymerase chain reaction (PCR). Vasculitis is a recognized feature of this infection involving capillaries, with consequent edema, necrosis, and lymphocytic infiltration. Therapy involves primarily doxycycline however other effective antibiotics include cefotaxime, penicillin, ampicillin, and amoxicillin.

Relapsing Fever

Relapsing fever is spread by tick or lice bites. Louse-borne relapsing fever is due to *Borrelia recurrentis*. Tick-borne relapsing fever is due to at least 15 different *Borrelia* species. Clinical illness is characterized by febrile episodes accompanied by prominent headache and myalgia. Neurologic involvement is characterized by meningitis, facial palsy, myelitis, radiculitis, and focal or diffuse CNS dysfunction [35]. Neuropathologic changes involve edema, subarachnoid, and parenchymal hemorrhage, with perivascular mononuclear infiltrates. Spirochetes can be found in the cerebral microvasculature and interstitial spaces. Diagnosis is based on culture and stain. Treatment includes administration of doxycycline, oxytetracycline, or cephalosporin.

Other Bacterial Agents

Mycoplasma

Mycoplasmas are very small bacteria that have a plasma membrane boundary, but lack a cell wall. The nervous system is a major extrapulmonary target, and neurologic disease can occur after primary atypical pneumonia or *de novo* [36]. Mycoplasma encephalitis reflects direct brain invasion or an immune-mediated syndrome. There is evidence for vascular injury and microthrombi, with endothelial cell infection [36, 37]. Stroke occurs in both children and adults [38]. Diagnosis is based on serology and PCR when positive. Therapy involves a

course of macrolide antibiotics, although neurologic involvement may be post-infectious and immune-mediated. Anticoagulation can be considered for thrombotic disease [].

Rosales and colleagues [38] described isolation of *Mycoplasma gallisepticum* and *synoviae* from the brains of poultry showing meningeal vasculitis and encephalitis, postulating a role for invasive mycoplasma species in human across the blood-brain barrier (BBB).

Bartonella

Bartonella are facultative gram negative intracellular bacteria that cause human and zoonotic disease. *Bartonella henselae* causes cat scratch disease. Several *Bartonella* species are associated with neuroretinitis, a retinal vasculitis. Immunocompromised hosts are vulnerable to more severe infections. *Bartonella* species can produce cutaneous and systemic vasoproliferative lesions [39]. *Bartonella henselae* is known to invade and colonize vascular endothelial cells, among others. Among a broad neurologic spectrum, there are rare cases of ischemic stroke and cerebral arteritis. Diagnosis is based on serology and PCR. Therapy involves doxycycline, or azithromycin.

Balakrishnan and colleagues [40] described isolation of *Bartonella henselae* DNA by PCR from a 12 year old's brain and blood with headaches, visual and auditory hallucinations, anxiety, vision loss, bouts of paralysis, facial palsy, chronic insomnia, seizures, dizziness, cognitive dysfunction, and memory loss resulting in cerebral infarction so noted on brain biopsy tissue, postulating cerebral vasculitis, however frank vasculitic lesions were not observed.

Tropheryma whippelii

Tropheryma (T.) whippelii, a member of gram positive Actinobacteria family, is the etiologic agent of Whipple disease is the soil-borne gram positive bacillus. CNS involvement, which occurs in up to 43% of cases, may be the initial presentation of infection in 5% of cases [41]. CNS involvement occurs in the setting of active Whipple disease, as well as in those relapsing previously treated disease, and isolated CNS involvement [42]. Stroke presentation, while very rare, has been described [43] and should be in the differential diagnosis of CNS vasculitis. Stroke also occurs with leptomenigeal arterial fibrosis and thrombosis, or associated with endocarditis [41]. Clues to diagnosis are extraneural disease including weight loss, fever, polyarthritis, diarrhea, and uveitis. Oculomasticatory myorhythmia and supranuclear gaze palsy are characteristic neurologic features. The diagnosis can be confirmed with PCR and tissue biopsy that reveals macrophages that stain positive for glycogen with the Periodic Acid Schiff (PAS) assay, or the identification of the causative organism by immunoreactive antigen. Effective treatment includes administration third generation cephalosporins followed by long-term, on average two years of trimethoprim-sulfamethoxazole (TMP-SMZ) and doxycycline.

Famularo and colleagues [44] identified arterial and arteriolar fibrosis, thrombosis, and thickening associated with inflammation of adjacent brain parenchyma and leptomeninges and cerebral vasculitis in a patient with cerebral Whipple's disease and stroke syndrome of without gastrointestinal involvement due to hematogenous spread of *Tropheryma whippelii*.

VIRAL PATHOGENS

Herpes Viruses

Herpes viruses are a large family of enveloped DNA viruses. Nine distinct agents affect humans, and all result in lifelong latent infection.

Varicella Zoster Virus

Varicella zoster virus (VZV) is the cause of childhood chickenpox and most children manifest only mild neurologic sequela, and an important infectious agent of associated blood vessel disease. After the infection resolves, the virus becomes latent in neurons of cranial and spinal ganglia of nearly all individuals, and has the propensity to reactivate in elderly adults and immunocompromised individuals to produce shingles. An uncommon but serious complication of virus reactivation is ischemic and hemorrhagic stroke. VZV vasculopathy affects both immunocompetent and immunocompromised individuals typically presenting with headache and mental status changes with or without focal neurological deficits and a spectrum of vascular damage from vasculopathy to vasculitis with stroke. Both large and small vessels can be involved and MRI shows multifocal ischemic lesions, commonly at gray-white matter junctions. The diagnosis of VZV can be missed when symptoms and signs occur months after zoster, or in the absence of a typical zoster rash.

It is the only virus documented to replicate in human arteries, and is a recognized risk factor for ischemic stroke in children, and stroke and TIA in adults under age 40 [45, 46]. It is latent in cranial nerve, dorsal root, and autonomic nervous system ganglia. VZV but when reactivated, spreads to arteries of the brain and spinal cord to produce a large and small vessel vasculopathy. Cerebral blood vessels show multinucleated giant cells, Cowdry type A inclusion bodies with viral particles, and detectable VZV antigens and DNA, consistent with direct infection. In one series of 30 patients [7], 50% had both large and small vessel involvement; 37% showed small artery involvement and 13% manifested large artery invasion [47]. Clinical sequela includes infarction, aneurysm, hemorrhage, and ICA dissection [48]. Recently, VZV vasculopathy was recognized as an etiologic agent in patients presenting with giant cell arteritis (GCA) in spite of non-informative temporal artery biopsy. Vascular involvement can be unifocal or multifocal. Both immunocompetent and immunocompromised hosts are affected, although more commonly it is the immunocompromised patient. Infarctions can be superficial or deep. Gray-white matter junction lesions are suggestive. With regard to primary infection, there are unusual cases of cerebral infarction or hemorrhage in children. With regard to reactivated infection, vasculopathy can occur up to 6 months after a zoster outbreak. Herpes zoster ophthalmicus (HZO) can be followed weeks later by delayed contralateral hemiparesis, with segmental carotid siphon arteritis, typically in immunocompetent individuals.

Small vessel involvement may lead to central retinal or posterior ciliary artery involvement, with monocular vision loss. Neuroimaging in these VZV cases is typically abnormal. CSF is often abnormal with an increase in WBC and RBC, raised CSF protein content and present oligoclonal bands. The CSF VZV IgG antibody should be measured along with a sample for PCR analysis however the former is more likely to be informative in true cases. CNS VZV vasculopathy often presents with headache and progressive neurologic

deficits without a history of zoster rash; rarely is VZV associated with spinal cord infarction. Treatment involves antiviral therapy with IV acyclovir however oral valcyclovir can be employed to extend the length of treatment in more profoundly affected or refractory cases due to concomitant HIV-infection.

Thirteen patients with VZV-related vasculopathy with detailed clinicopathologic data including histological findings of vasculitis have been described in the literature. VZV DNA and VZV-specific antigen were found in three of five cerebral arteries examined with histologically-confirmed CNS vasculitis involving the circle of Willis. Patient 1 of Eidelberg and colleagues [49] who presented with headache and herpes zoster ophthalmicus (HZO) rash was deemed to have CNS vasculitis based upon complete occlusion of the MCA and so treated, however postmortem examination showed no evidence of vasculitis. One patient with contralateral hemiplegia one month after HZO was found at postmortem examination to have endarteritis of unilateral ACA, MCA and PCA [50] with VZV DNA from the involved vessels.

Cytomegalovirus

Cytomegalovirus (CMV) replicates in leukocytes and vascular endothelial cells during primary infection with single patient reports of CMV associated with vasculitis. Venous involvement can be found in addition to occlusive arteritis. Affected individuals are usually HIV-positive or an immunocompromised host [51]. Diagnosis involves serological studies, PCR, culture, and histopathological tissue analysis for the causative organism. Therapy includes IV ganciclovir, foscarnet, or a combination of both. One recently described elderly woman with CMV encephalitis [52] later developed a post-infectious primary CNS vasculitis.

Koeppen and coworkers [53] described rapidly progressive CNS and peripheral nervous system (PNS) deterioration two years after chemotherapy for small cell undifferentiated lymphoma in whom postmortem examination demonstrated occlusive arteritis in gray and white matter with involvement of veins indicative of vasculitis, in addition to Cowdry A inclusions and chorioretinitis.

Herpes Simplex and Epstein-Barr Virus

Herpes simplex virus (HSV), types 1 and 2, and *Epstein Barr virus* (EBV) have been associated with CNS vasculitis [54, 55], however vessel wall contrast enhancement may be a clue in suspected patients [55] and a positive findings in CSF PCR is adequate to justify antiviral therapy. However, in contrast to VZV where reactivation is the mechanism of causation, CNS vasculitis may be problematic due to latency of infection. Kano and colleagues [56] described EBV-associated CNS vasculitis in brain biopsy tissue of a patient with rapid CNS deterioration and positive EBV DNA in CSF.

Retroviruses

Human Immunodeficiency Virus

Approximately 1% to 5% of individuals infected with human immunodeficiency virus (HIV) are at risk of developing a stroke due to opportunistic infections, coagulopathy, cardioembolism, HIV-associated vasculopathy and frank vasculitis [57]. Moreover, HIV-

associated arterial vasculitis is believed to account for 13% to 28% of ischemic strokes. CNS vasculitis which is estimated to occur in less than 1% of cases of HIV infection is a diagnosis of exclusion. Typically patients are in an advanced stage of the infection. HIV can be associated with a granulomatous inflammation involving small arteries and veins within the brain and leptomeninges. HIV patients with vasculitis should be assessed for cryoglobulins and accompanying infection especially TB, syphilis, CMV, VZV, hepatitis B and C virus (HBV and HCV), or a drug induced vasculitis. Therapy typically involves highly active antiretroviral therapy (HAART), with corticosteroids reserved for refractory cases due to vasculitis.

Early in the HIV and the acquired immune deficiency syndrome (AIDS) epidemic, it was clear that a significant proportion of infected persons were intravenous drug users. Their associated risk behavior exposed them to infection through sharing of contaminated needles thereby increasing the risk of spread of HIV and other blood borne infections. The two postulated periods in the neurobiology of HIV when autoimmune disease manifestations and cerebral vasculitis can occur are shortly after seroconversion and before the spread of productive infection, and after initiation of HAART in association with the immune reconstitution inflammatory syndrome (IRIS). The timing of early HIV invasion has been difficult to ascertain based on the presence of one or well-recognized clinicopathological HIV/AIDS syndromes including HIV encephalitis, HIV-associated dementia and AIDS-dementia complex, all of which are indicative of symptomatic infection. Six presymptomatic HIV-seropositive drug abusers by Gray and colleagues [58] had non-necrotizing cerebral vasculitis at postmortem examination.

HTLV-1

Human T-cell lymphotropic virus-type 1 (HTLV-1) was the first described human retrovirus. It causes adult T-cell leukemia and lymphoma, as well as a progressive myelopathy referred to as tropical spastic paraparesis-HTLV-1 associated myelopathy in less than 1% of infections. Neurological syndromes associated with HTLV-1 infection appear to be due to active and selective expansion of retrovirus infected T-cells that harbor provirus that selectively express HTLV-1 proteins such as Tax. In particular, activated cytotoxic CD8⁺ T cells are increased. Perivascular inflammation is a frequent histopathological feature. The laboratory diagnosis of HTLV-1 infection is based on serological and PCR studies. There is no proven antiviral therapy. Ma and coworkers [59] reported vasculitis in brain biopsy tissue of a patient with HTLV-1 infection.

Hepatitis Agents

Hepatitis C is estimated to affect 170 million people worldwide with extrahepatic involvement that occurs in 38% to 74% of cases. Hepatitis C is associated with cryoglobulinemia, arthritis, and palpable purpura. There is an immune response to the Fc portion of immunoglobulin, characterized by the Wa idiotype. The resulting immune complex which contains virus, idiotypic antibody, and antibody precipitates in the cold and produces a small vessel vasculitis. HCV can cause CNS vasculitis independent of cryoglobulinemia, and CNS vasculitis may be the first clinical manifestation of hepatitis C infection.

Affected patients present with progressive headache, multiple strokes, and typical angiographic patterns. Therapy includes the antiviral agents interferon (IFN), ribavirin, sofosbuvir, protease inhibitors, and corticosteroids. Both HBV and HCV have been associated with polyarteritis nodosa (PAN) [60] that typically involves the peripheral nervous system (PNS), but unusual cases may involve the CNS. In such cases antiviral therapy is added to corticosteroids, and cyclophosphamide in more severe cases. This might involve the virostatic agent lamivudine or INF-alpha for HBV and ribavirin for HCV [61]. Plasma exchange and rituximab can be added in specific cases as needed.

Parvovirus B19

Parvovirus B19 is a small non-enveloped DNA virus that only infects humans. It causes erythema infectiosum also known as fifth disease, a benign childhood condition characterized by a classic slapped-cheek appearance. It can cause anemia with pre-existing disease as well as arthritis. The cellular receptor for parvovirus B19 is an antigen of the P blood group present on endothelial cells and erythroid progenitor cells. Rare patients with CNS vasculitis have been reported in association with Parvovirus B19 infection [62]. The diagnosis is based on serological studies and PCR testing. There is no specific antiviral therapy for Parvovirus B19 infection; however both intravenous immune globulin (IVIG) and corticosteroids have been used therapeutically.

West Nile Virus

West Nile virus is a flavivirus typically transmitted by the bite of infected culex mosquitos. Less than 1% of patients develop invasive neurological disease that includes meningitis, encephalitis, and resultant flaccid paralysis, with rarely reported cases of ischemic infarction and CNS vasculitis [63-65] and occlusive retinal artery vasculitis. Patients with a history of diabetes and alcohol abuse, and older individuals are at increased risk for ischemic complications. Diagnosis is based on IgM antibody and viral RNA detection, as well as virus isolation. There is no antiviral therapy, but IVIG has been beneficial in individual patients.

Zika Virus

Zika virus is an arbovirus belonging to the *Flaviviridae* family. Younger has reviewed the epidemiology of Zika virus [66]. Originally isolated in Uganda, known to cause mild clinical symptoms similar to those of dengue and chikungunya, Zika is transmitted by different species of *Aedes* mosquitoes. Non-human primates and possibly rodents play a role as reservoir. Direct interhuman transmission has been reported to occur perinatal, through blood transfusion and sexually. The first human cases were reported in Africa and, but recent outbreaks in several regions of the world including including Brazil, highlighted the needs of the scientific and public health community to consider it as an emerging global threat.

Its clinical profile is that of a dengue-like febrile illness but recently associated Guillain-Barre syndrome and microcephaly have appeared. There is neither a vaccine nor prophylactic medications available to prevent Zika virus infection so current public health recommendation advise pregnant women to postpone travel to areas with Zika viral infection is epidemic, and if not, to follow steps to avoid mosquito bites to avert fetal brain injury associated with intrauterine infection. Viral RNA indicating Zika virus, Chikungunya virus, and Dengue infection can be pathogenically isolated from the CSF of adults with neurological symptoms with meningitis or encephalitis, Guillain-Barré Syndrome, and CNS vasculitis.

FUNGAL PATHOGENS

Aspergillus

Aspergillosis is the most common invasive mold infection worldwide. It typically causes disease in immunocompromised hosts, although CNS vasculitis and stroke occur in immunocompetent patients [67, 68]. The major human pathogens are from the *Aspergillus fumigatus*, *niger* and *flavus* species. Patients with hematologic malignancies and a history of bone marrow transplantation can have fulminant CNS courses with mortality rates of 85% to 99% [4].

The *Aspergillus* organisms invade blood vessels with resultant production of proteases that weaken the vessel wall leading to aneurysm formation [69]. The course can be more chronic and insidious in those with lesser degrees of immune compromise, such as due to diabetes mellitus. Spread to the CNS occurs via hematogenous routes from the lung, or by direct extension through the paranasal sinuses and orbits. CNS involvement which occurs in 10% to 50% of systemic infections includes meningoencephalitis and intracerebral hemorrhage, as well as, vasculopathy, and mycotic aneurysm formation leading respectively to stroke and potentially fatal subarachnoid hemorrhage with greater involvement of penetrating than larger named vessels.

Aspergillus infection should be considered in immunocompromised hosts with pulmonary disease and either ischemic or hemorrhagic stroke. The diagnosis can be difficult since CSF cultures are positive in less than 50% of cases, and PCR is investigational. Two antigen assays, each for biomarkers including galactomannan and beta-D-glucan, have not been standardized in the CSF. Tissue biopsy can be confirmatory. Brain neuroimaging may demonstrate ring-enhancing lesions, meningeal enhancement, and ischemic or hemorrhagic stroke. Therapy involves oral voriconazole and surgical resection of focal cerebral and extraneural sites of involvement.

Candida

Candida species are part of normal human flora and thus typically are not pathogenic unless there is mitigating systemic immune compromise. Neutropenia is a major risk factor for invasive disease. *Candida* is considered a yeast infection with *Candida albicans* the most common agent in humans. It invades small blood vessels and can be associated with

thrombosis and infarction. Neurologic involvement most often takes the form of meningitis that may predispose to basilar artery thrombosis [70]. One affected patient with HIV/acquired immune deficiency virus syndrome (AIDS) and subacute meningitis who was treated empirically for tuberculosis and initiated on HAART therapy developed fatal worsening due to postmortem-proven basilar *Candida* meningitis and cerebral vasculitis characterized by CD8+ T-cell infiltration and microinfarcts, consistent with IRIS [77]. The diagnosis of *Candida* infection is based on a positive culture and informative PCR, and suggestive findings on antigen assays to mannan and beta-D glucan albeit not routinely performed. Effective treatment depends upon the age and severity of infection with lipid formulations of amphotericin, fluconazole, or echinocandin.

Lipton and colleagues [71] described CNS vasculitis at postmortem examination in 48% of 29 patients with systemic candidiasis, only 21% of whom had suspected antemortem involvement noting that immunosuppression represent a risk factor for both systemic and cerebral mycoses.

Coccidioides immitis

Coccidioides immitis is a soil based fungus endemic to the arid Southwest and Latin America. Infection may be asymptomatic or the cause of mild pulmonary issues such as occurs in valley fever. About one-half of disseminating cases involve the CNS resulting in basilar meningitis with a local vasculitis of small and medium arteries, and occasionally larger ones that is more likely to occur in immunocompromised hosts [72]. Cerebral infarction complicates about 40% of patients with *coccidioides* meningitis leading to alteration of mental status and emergency of focal deficits [4]. Stroke can occur years later following the initial infection [72]. In general, acute infectious related injury can predispose to vasculitic changes that include transmural inflammation with thrombosis and fibrinoid necrosis, while chronic injury leads to intimal thickening, proliferation, and narrowing of the lumen with little or no inflammation.

CSF culture is positive in 33% of cases, often in association with eosinophilic pleocytosis. Complement fixation is positive in about 40% of serum and CSF specimens, but seroconversion can take up to 12 weeks. Treatment involves high-dose fluconazole followed by maintenance therapy. Voriconazole is a second line agent. A self-limited course of corticosteroids can be given in the setting of cerebral infarction to reduce inflammation.

Eron and colleagues [73] described vasculitis and encephalitic as a complications of *Coccidioides immitis* infection of the CNS in six cases of apparent, and four cases of histologically proven vasculitis, including one with vasculitis and encephalitis associated with coccidioidal meningitis. Vasculitic complications includes mental status changes, aphasia, hemianopia, and hemiparesis.

Cryptococcus neoformans

The yeast form, *Cryptococcus neoformans* is the commonest cause of fungal meningitis [4]. Vessels of the circle of Willis are most affected by the resultant basilar exudate. Vascular involvement occurs early or late in 4% to 32% of cases. Diagnosis is made by the presence of CSF cryptococcal antigen, India ink stain, and culture. Treatment involves induction therapy with intravenous amphotericin and flucytosine for 2 weeks followed by consolidation with fluconazole once CSF cultures are negative. Corticosteroids may offer a benefit in the setting of stroke [74].

Exserohilum rostratum

Exserohilum rostratum is a dematiaceous fungus and black mold that does not typically cause human disease. It is a major contaminant in iatrogenic infections due to mold contamination of methylprednisolone acetate. There was one fatal case of meningitis and CNS vasculitis in an immunocompetent host who received a cervical epidural steroid injection for chronic neck pain [80]. The diagnosis is based on culture and PCR of CSF. Recommended therapy is liposomal amphotericin B and voriconazole, with monitoring of drug levels [75].

Lyons and colleagues [76] described angioinvasive septate fungal hyphae associated with diffuse vasculitis at postmortem examination in the brainstem of a patient with fatal *Exserohilum* meningitis following cervical epidural methylprednisolone injection for new occipital headaches.

Histoplasma capsulatum

Histoplasma capsulatum is a dimorphic fungus that is endemic in the Ohio and Mississippi River Valley, as well as parts of Latin America, Asia, and Africa [4, 77]. Although infection in immunocompetent hosts may remain asymptomatic or lead to mild lower respiratory tract illness, others can experience disseminated infection with CNS involvement in up to 20% of cases. The latter most commonly manifests meningitis however strokes may accompany associated infective *histoplasma* endocarditis or associated meningovascular disease with ensuing mortality of 11% to 100%. CSF culture and antigen studies which show evidence of CNS infection can be supported by anti-histoplasma antibodies. Treatment includes liposomal amphotericin followed by itraconazole or fluconazole for at least one year.

Mucormycosis

Mucormycosis is due to infection by filamentous fungi of the order *Mucorales* and class *Zygomycetes*. They are ubiquitous organisms in bread mold, soil, manure, and decaying vegetation, and the second commonest invasive mold infection [78, 79]. *Rhizopus*, *Mucor*, and *Lichtheimia* are the most common genera to cause mucormycosis. Immunocompromised hosts are at particular risk. Underlying conditions include diabetes mellitus, hematologic malignancy, trauma, solid cancers, and solid organ transplants.

Sites of infection include lung, skin, gastrointestinal tract, and the rhino-orbito-cerebral region. Iron is an important component in this infection. These fungi contain spore coat homolog proteins that are unique, and required for angioinvasion. The result of this blood vessel invasion is vessel thrombosis and tissue necrosis. The rhino-orbito-cerebral form may produce suggestive necrotic nasal or sinus eschars. Patients may experience carotid or basilar artery thrombosis, cavernous sinus thrombosis, or intracerebral hemorrhage [80, 81].

Diagnosis is based on clinical suspicion confirmed by biopsy, scraping, or culture. PCR is being evaluated. Treatment involves a combination of surgery and systemic therapy. Liposomal amphotericin B is favored therapy however thiazoles and posaconazole antibiotics have been used in selected individuals.

PARASITIC PATHOGENS

Taenia solium

Cysticercosis due to infection with the larval stage of the pork cestode tapeworm *Taenia solium* is the commonest CNS parasite accounting for 10% of stroke cases in endemic areas, and a major cause of headache and seizures. Lenticular striate lacunar infarcts are more common than large artery stroke, however TIA and intracranial hemorrhages also occur [4, 82-84]. Among 28 patients with subarachnoid cysticercosis, 15 (53%) had angiographic evidence of cerebral arteritis, 12 (80%) of whom had a stroke syndrome ($P=0.02$). Eight of the 15 patients (53%) with cerebral arteritis had evidence of cerebral infarction on MRI, whereas only one patient without cerebral arteritis had cerebral infarction ($P=0.05$). The most commonly involved vessels were the MCA and posterior cerebral artery (PCA). Small vessels are preferentially affected, with superficial cortical vessel thrombosis, occlusive endarteritis, and focal arteritis. Larger circle of Willis vessels are involved when severe arachnoiditis is present. Diagnosis involves antibody testing and suggestive findings on neuroimaging; however antigen testing is not routinely used. Anti-helminthic therapies include the benzimidazole drug albendazole and the anti-helminthic drug praziquante with corticosteroids.

Plasmodium falciparum

Plasmodium falciparum is a unicellular parasitic protozoan that infects humans causing more severe forms of malaria. The disease is typically transmitted by the bite of an infected female *Anopheles mosquito*. Inoculated sporozoites infect and multiply in liver cells, then differentiate into merozoites that are released and invade red blood cells. Infection leads to expression of adhesive surface proteins that cause the red cells to stick to the walls of small blood vessels. Intercellular adhesion molecule (ICAM)-1 is a major host binding site.

Falciparum malaria is a leading cause of morbidity and mortality in tropical countries. Cerebral malaria is the most severe neurologic manifestation]. It is defined by coma that is not due to seizures, hypoglycemia, or any other identifiable cause, and that is associated with a positive blood smear for parasitized red blood cells.

Pathophysiology is believed to be due to parasitic sequestration in cerebral microvessels. As infected red cells adhere to the endothelium, they cause further erythrocyte agglutination along with platelet clumping. There is endothelial activation, and direct cytotoxic injury. Perfusion is abnormal, and tissue oxygenation is compromised. There may also be injury mediated by soluble factors including various chemokines, cytokines, nitric oxide, and quinolinic acid. Diagnosis is based on blood smear, and antigen-based rapid diagnostic tests. Patients diagnosed with uncomplicated malaria can be effectively treated with the oral antimalarial drug chloroquine phosphate (Aralen™) or hydroxychloroquine (Plaquenil™). Patients who are considered to have severe disease should be treated aggressively with parenteral antimalarial therapy. Treatment of severe malaria involves parenteral quinidine gluconate given by continuous infusion for at least 24 hours in an intensive care setting plus

one of the following: doxycycline, tetracycline or clindamycin orally or IV followed by oral administration for a full course of seven days.

There is an investigational new drug protocol that can be obtained by contacting the Centers for Disease Control and Prevention (CDC) that employs artesunate followed by one of the following: atovaquone-proguanil (MalaroneTM), doxycycline (clindamycin in pregnant women), or mefloquine (LariamTM).

Schistosoma mansoni

This Trematoda infection which involves a flatworm is endemic to sub-Saharan Africa and South America. There is percutaneous penetration of cercariae in the invasive stage followed by mating worms that inhabit the inferior mesenteric veins where they excrete eggs in the adult stage. Neurologic involvement occurs in later stages of infection wherein adult worms can be found in spinal meningeal veins and the intracranial venous system [94]. Ectopic eggs migrate to the brain provoking granuloma formation. Cerebrovascular lesions are found in 20% of patients from postmortem series.

CNS vasculitis occurs in both early and later stages of *Schistosoma* infection [85, 86] associated with multiple infarctions, marked eosinophilia, and a corticosteroid response reflective of eosinophil-mediated injury. Presumptive diagnosis is suggested by a known travel history and compatible clinical presentation combined with serological testing and documentation of eggs in the stool. Treatment involves praziquantel.

Toxoplasma gondii

Toxoplasma gondii is an obligate intracellular protozoan that causes toxoplasmosis. During the initial acute phase of the infection, rapidly dividing tachyzoites spread throughout the host. The development of an effective cellular immune response suppresses the replication of tachyzoites and eradicates most of them, ending the acute phase of the infection. In the brain, the parasites undergo conversion to bradyzoites, which remain viable in the form of cysts because of the low levels of class I MHC and, in addition, the parasites within the cyst are surrounded by the parasitophorous vacuole that is enclosed by a cyst wall, thus little antigen escape into the cytoplasm of the cyst-containing host cell. The organisms reproduce slowly throughout the life of the host and can remain viable within intact nerve cells. Cyst rupture occurs rarely and, in immunocompetent individuals, a rapid immune response leading eventually to microglial nodule formation limits the damage to small inflammatory foci. However, in immunocompromised hosts, cyst rupture may reactivate the infection, leading to the conversion of bradyzoites to the active and rapidly replicating tachyzoites and development of severe tissue injury. Therefore, the CNS may be affected in congenital toxoplasmosis, as a primary infection in immunocompetent individuals, or as an opportunistic infection in immunosuppressed individuals. Thus, most CNS infections represent reactivation of old lesions and hematogenous spread from prior infections instead of primary infection.

The resulting disease is widely distributed worldwide among domestic animals and humans. The oocyst form is excreted in cat feces and can be the source of infection. Eating

infected raw or undercooked meat is another source of infection. Most infections are asymptomatic however immunocompromised hosts are particularly vulnerable to clinical disease. Toxoplasmosis is the leading cause of focal CNS disease in patients with HIV/AIDS and low CD4+ T-cell counts.

Congenital toxoplasmosis causes the characteristic eye lesion termed chorioretinitis, cerebral calcifications, hydrocephalus, and CSF pleocytosis. The pathological features include periventricular microglial nodules surrounded by lymphocytic vasculitis and necrotic foci. Toxoplasma encephalitis shows well circumscribed areas of hemorrhage and necrosis, with vascular thrombosis and present tachyzoites. The resulting clinical presentation is usually headache with constitutional symptoms that progress to encephalopathy and focal neurological deficits.

Toxoplasmosis as an opportunistic infection in immunosuppressed individuals has been reviewed by Pittella [87]. In HIV-infected patients, the disorder presents as a mass lesion, usually multiple, with the basal ganglia, thalamus, and the cerebral gray and white matter junctions being the preferred sites. The lesions consist of well-defined areas of coagulative necrosis, with or without hemorrhage, containing karyorrhectic debris. Blood vessel changes are common, characterized by necrosis, vasculitis, and thrombosis. Mononuclear inflammatory cells and reactive astrocytes in variable numbers are seen surrounding the necrosis. Bradyzoites and tachyzoites are present in large numbers, the former at the periphery of the lesion and the latter within the necrosis. The immunohistochemical identification of tachyzoites is especially useful when bradyzoites are not seen. In more chronic lesions, macrophages may surround the necrosis associated or not with calcification and parasites are reduced in number. In treated patients, the lesions undergo cystic change and are surrounded by macrophages, scanty inflammatory infiltrate, and astrocytosis.

Serological testing is generally positive, but may not be so in immunocompromised patients. Parasites can sometimes be observed in biopsy-stained tissues and CSF however a positive CSF PCR is helpful. Culture is typically too time-consuming to perform. Compatible features of the disorder on brain MRI include single or multiple lesions in the basal ganglia and white matter, with mass effect and homogeneous or ring enhancing lesions. However, brain neuroimaging may also be normal when there is diffuse CNS involvement.

Treatment includes pyrimethamine, sulfadiazine, and folinic acid administered for six weeks and treatment of any underlying immunocompromised condition. Alternative therapy includes trimethoprim-sulfamethoxazole and clindamycin for patients allergic to sulfa medication.

RICKETTSIAL PATHOGENS

Rickettsiae (R.) are obligate intracellular gram negative coccobacillary agents that multiply in eukaryotic cells. Phylogenetically they fall between bacteria and viruses. Both mammals and arthropods are natural hosts. Within the genus *rickettsiae*, there are three biogroups that cause illness: the spotted fever group, the typhus group, and the scrub typhus biogroup. *Rickettsiae* adhere to, and invade endothelium with increased vascular permeability, leakage, edema, and hypotension. They are capable of eliciting a generalized vasculitic response in the CNS.

Rickettsia rickettsiae

R. rickettsia cause Rocky Mountain spotted fever (RMSF). More than 90% of infections in the United States occur from April through September via tick bite. The tick vectors are larger soft ticks including *Dermacentor andersoni* and *variabilis*; and *Amblyomma americanum*. Within the CNS the vasculitis provokes a damaging immune response that is predominantly cell-mediated. The overall associated mortality rate is about 4%.

Symptomatic infection involves severe headache, abdominal pain, persistent fever, peripheral macular centripetal rash, confusion and myalgia. The classic triad is fever, headache, and rash. Conjunctivitis may also be noted. Neurologic involvement includes meningoencephalitis, focal deficits, and coma. Suggestive laboratory abnormalities are thrombocytopenia, hyponatremia, and elevated liver enzymes. A deficiency of glucose -6-phosphate dehydrogenase enzyme is associated with more severe infection.

Diagnosis is made on clinical grounds, confirmed by positive serology. Therapy involves doxycycline for 7 to 14 days.

Kumar and Pramod [88] described a young Indian male with high fever and severe acute headache followed by mental change who developed facial weakness, hyperreflexia and right posterior cerebral and bilateral thalamopeduncular infarcts on computerized tomography (CT) of the brain, with filling defects in the origin in the P1 segment of the right PCA on CTA. CSF showed lymphocytic pleocytosis and a positive Weil-Felix test for the proteus antigen OX19. The patient was diagnosed with cerebral vasculitis, however confirmatory histopathology was not obtained.

Scrub Typhus

Scrub typhus (Tsutsugamushi disease) involves infection with different species of *Orientia tsutsugamushi*. Most cases occur in the southwest Pacific and Southeast Asia. Infection occurs with the bite of the larval form of trombiculid mites or chiggers, resulting in small vessel perivasculitis. The ensuing illness is typically mild and self-limited, but can progress to life-threatening neurological illness [89-91] including meningoencephalitis. Suggestive features of the disorder include necrotic eschar at the site of the mite bite so noted in 50% of case; generalized lymphadenopathy, and mild truncal rash. CSF shows a pattern of aseptic meningitis. Serologic testing is available, and therapy involves doxycycline or another tetracycline.

CONCLUSION

Underlying infections are important to consider in patients with CNS vasculitis and when seriously suspected warrant prompt and thorough investigation. Selected antimicrobial therapy combined with supportive care can be life-saving however a self-limited course of corticosteroids can lead to prompt reduction in associated inflammation and preservation of neurological integrity.

ABSTRACT

The vasculitides are diverse disorders characterized by inflammation of vessel walls resulting in damage to the mural structures and ischemic injury. Necrotizing vasculitic lesions of peripheral nerve microvessels measuring 75 to 300 microns in diameter impact small arteries, large arterioles, and variably smaller vessels in the majority of primary and secondary systemic vasculitis. Microvasculitis is distinguished by transmural non-necrotizing inflammatory lesions affecting the smallest arterioles typically less than 40 microns, impacting smaller arterioles, endoneurial capillaries, and venules. These histopathological features are characteristic of several primary and secondary disorders, including nonsystemic vasculitic neuropathy and the interrelated disorders of diabetic and non-diabetic lumbosacral radiculoplexus neuropathy, diabetic cervical radiculoplexus neuropathy, and painless diabetic motor neuropathy. The resultant clinical features in each of these vasculitic entities depend on the size of the vessels involved, the severity of the inflammatory process, and the location and cumulative extent of the lesions along the peripheral nerve.

In light of these observations, we favor a simplified binary clinicopathological classification of vasculitic neuropathy based upon the size of the affected vessels, and the separation into the broad categories of nerve large arteriole vasculitis and microvasculitis. Such categorization informs prognosis and the approach to treatment. This chapter

* Corresponding Author's Email: DyckPJJames@mayo.edu.

reviews the essential aspects of the nosology and classification, clinicopathologic aspects, prognosis and selected management of the representative vasculitides.

Keywords: primary, secondary, vasculitic, systemic, non-systemic, radiculoplexus, diabetic, painless, motor, lumbosacral, microvasculitis

INTRODUCTION

Vasculitis of the peripheral nerves occurs when the walls of arteriae nervorum and other nerve microvessels are infiltrated and damaged by inflammatory cells with secondary ischemic injury [1]. Vasculitic processes may be systemic or restricted to the nerves. Systemic vasculitis is primary or secondary to other disorders such as a connective tissue disease, infectious process, paraneoplastic syndrome, or drugs [2, 3]. This chapter examines the classification, diagnosis, clinical features, and treatment of common primary and secondary systemic vasculitic neuropathy (SVN), non-systemic vasculitic neuropathy (NSVN), and other recently described radiculoplexus neuropathies, including diabetic lumbosacral radiculoplexus neuropathy (DLRPN) and non-diabetic LRPN, diabetic cervical radiculoplexus neuropathy (DCRPN), and painless diabetic motor neuropathy (PDMN).

Classification

There are several accepted classification schemes for systemic vasculitic neuropathy based on the clinical characteristics, histopathological features and underlying mechanisms. Over the last several decades the classification schemes have become gradually more complex due to the increasing number of disorders considered to be vasculitic [4–9]. Additional studies to further define the optimal classification scheme are ongoing [10].

In 2010, the Peripheral Nerve Society Task Force [4] proposed a classification scheme that categorized SVN into primary and secondary forms, NSVN, and other localized presentations (Table 1). In this classification pathologically-definite vasculitic neuropathy must meet the pathological criteria for an active or chronic lesion. The former required demonstration of cellular invasion of the walls of blood vessels and one or more signs of active vascular damage, including fibrinoid necrosis, endothelial loss/disruption, internal lamina loss/fragmentation, smooth muscle media loss/fragmentation/separation, acute thrombosis, vascular/perivascular hemorrhage or leukocytoclasia (Figure 1). Chronic vasculitic lesions require demonstration of chronic vascular damage with repair, including intimal hyperplasia, fibrosis of media, adventitial/periadventitial fibrosis or chronic thrombosis with recanalization. Non-systemic vasculitic neuropathy require pathology to be isolated to the peripheral nerves. The Peripheral Nerve Society guideline group adopted two new exclusionary criteria for NSVN, both with >95% specificity for SVN, namely antineutrophil cytoplasmic antibodies (ANCA) and erythrocyte sedimentation rate (ESR) >/100 mm/h [4].

Table 1. Classification of peripheral neuropathy-associated vasculitides

I. Primary systemic vasculitides
1. Predominantly small vessel vasculitis
a. Microscopic polyangiitis
b. Eosinophilic granulomatosis with polyangiitis
c. Granulomatosis with polyangiitis
d. Essential mixed cryoglobulinemia (non-HCV)
e. IgA vasculitis
2. Predominantly medium vessel vasculitis
a. Polyarteritis nodosa
3. Predominantly large vessel vasculitis
a. Giant cell arteritis
II. Secondary systemic vasculitides associated with one of the following
1. Connective tissue diseases
a. Rheumatoid arthritis
b. Systemic lupus erythematosus
c. Sjögren syndrome
d. Systemic sclerosis
e. Dermatomyositis
f. Mixed connective tissue disease
2. Sarcoidosis
3. Behcet disease
4. Infection due to HBV, HCV, HIV, CMV, leprosy, Lyme disease, and HTLV-I
5. Drugs
6. Malignancy
7. Inflammatory bowel disease
8. Hypocomplementemic urticarial vasculitis syndrome
III. Non-systemic/localized vasculitis
1. Non-systemic vasculitic neuropathy, including non-diabetic radiculoplexus neuropathy and some cases of Wartenberg migrant sensory neuritis
2. Diabetic radiculoplexus neuropathy
a. Diabetic lumbosacral radiculoplexus neuropathy
b. Diabetic cervical radiculoplexus neuropathy
c. Diabetic thoracic radiculopathy
d. Painless diabetic motor neuropathy
3. Localized cutaneous/neuropathic vasculitis
a. Cutaneous polyarteritis nodosa
b. Others

Abbreviations: ANCA, anti-neutrophil cytoplasmic antibody; CMV, cytomegalovirus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus.

The Revised 2012 Chapel Hill Consensus Conference (CHCC) [5], which categorized the diverse forms of primary and secondary systemic vasculitis based upon the caliber of the vessels involved and the associated clinicopathologic features, did not directly consider NSVN. However, under their nosology [5], NSVN would be designated a single-organ vasculitis (SOV) of the peripheral nervous system (PNS), analogous to primary central nervous system (PCNS) vasculitis. Peripheral nerve involvement is distinctly uncommon in large vessel vasculitis that affects the aorta, its major branches and analogous veins. It is more prevalent in polyarteritis nodosa (PAN) which involves medium and small caliber vessels, notably visceral arteries and veins and their initial branches and small vessel vasculitis in

association with ANCA and immune complexes, with involvement of intraparenchymal arteries, arterioles, capillaries, veins and venules. The category of ANCA-associated vasculitis (AAV) includes granulomatosis with polyangiitis (GPA), eosinophilic granulomatosis with polyangiitis (EGPA) and microscopic polyangiitis (MPA), while vasculitic disorders associated with immune complexes include IgA vasculitis, cryoglobulinemic vasculitis, and hypo-complementemia urticarial vasculitis associated with C1q antibodies. There were in addition, separate categories for vasculitis associated with specific systemic connective tissue disorders such as rheumatoid arthritis and Sjögren syndrome, and disorders associated with a known systemic disorder such as might occur in paraneoplastic and infection-related vasculitis. Drug-related vasculitic neuropathies comprise a separate secondary systemic vasculitic neuropathy category.

Figure 1. Serial transverse paraffin sections of a sural nerve biopsy showing larger arteriole necrotizing vasculitis: Panel A (H&E) and B (Mason's trichrome) shows fibrinoid necrosis of the mural elements with inflammatory infiltration, orange discoloration (arrows), luminal occlusion and vessel wall destruction. Panel C (CD45) confirms the leukocyte infiltration and panel D (smooth muscle actin) shows the fragmentation and destruction of muscle layers with loss of normal architecture.

We favor a simplified binary classification of vasculitic neuropathies based on the size of the affected vessels into nerve large arteriole vasculitides and microvasculitis. This classification scheme is valuable as the prognosis and treatment approach differs between these two groups. The former category, which affects vessels ranging from 75 to 300 microns in diameter, involves small arteries, large arterioles and variably smaller vessels. As virtually all peripheral nerve vessels, even the largest intraneural arteries, can in a general sense be considered small vessels, it is possible to group most patients with PAN, AAV, and secondary vasculitis associated with connective tissue disease, infection and paraneoplasia in nerve large

arteriole vasculitis [7]. By comparison, nerve microvasculitis, which includes DLRPN, LRPN, DCRPN and PDMN, involves small arterioles, endoneurial microvessels, capillaries and venules all measuring less than 40 microns. Nerve large arteriole vasculitis typically demonstrates fibrinoid necrosis, whereas microvasculitis is differentiated by inflammation in the vessel wall with fragmentation and necrosis of the tunica media (Figure 2). Common features to both forms of vasculitis include multifocal fiber loss, perineurial thickening, hemosiderin-laden macrophages, active Wallerian degeneration, neovascularization, and immune deposits of IgM, complement proteins, and fibrinogen in the epineurial vessel walls. The overlap of vessel size in NSVN was anticipated in the Revised 2012 CHCC (5), nonetheless most cases of NSVN fit better into the microvasculitis than the nerve large arteriole vasculitis category.

Figure 2. Serial transverse paraffin sections (panels A, C, and D) and an epoxy section (panel B) of a sural nerve showing nerve microvasculitis: Panel A (H&E) shows inflammation surrounding and involving two vessel walls (arrows), panel B (methylene blue) shows multifocal fiber loss with the upper right fascicle showing fiber degeneration and loss (typical ischemic injury) that can result from both large arteriole necrotizing vasculitis and microvasculitis, panel C (CD45) shows the transmurial inflammation is mostly leukocytes (lymphocytes [arrows]), and panel D (smooth muscle actin) shows fragmentation and disruption of the muscular layers of vessel walls (arrows).

Clinical Features

The clinical presentation of a vasculitic neuropathy depends on the distribution and severity of blood vessel involvement. Patients with primary and secondary systemic vasculitis typically manifest severe multiorgan symptoms that can overshadow the peripheral nervous

system involvement. However, one-quarter of patients with PAN and AAV may have neuropathy as a heralding feature [11]. Patients typically display constitutional symptoms including weight loss, fatigue, fever, rash or night sweats. Other organs may also be involved with evidence of respiratory symptoms, skin manifestations, gastrointestinal symptoms, and hematuria [12–15]. In contrast, NSVN is not accompanied by extraneural involvement, although constitutional symptoms such as fatigue, weight loss, arthralgia, and myalgia occur in up to one-third of patients [4, 9].

Patients with both SVN and NSVN will typically present with acute to subacute onset of painful sensory or sensorimotor mononeuropathies followed by stepwise involvement of other nerves resulting in mononeuropathy multiplex (otherwise known as multiple mononeuropathy). Some patients have a fulminant presentation, whereas others have a more slowly progressive form and may go undiagnosed for up to a decade or longer, especially those reported with NSVN [16, 17]. Although vasculitic neuropathies are classically associated with a multiple mononeuropathy presentation, a given patient may demonstrate overlapping mononeuropathies that instead resemble distal predominant symmetrical or asymmetrical polyneuropathy [2, 13]. The pattern frequencies are multifocal neuropathy, 45%; asymmetric neuropathy, 35%; and distal symmetric polyneuropathy, 20% (4,18). One-third of patients present with slowly progressive neuropathy that does not develop in a stepwise fashion [19–21]. Vasculitis has a predilection for particular nerves including the common fibular mixed nerve, the fibular division of the sciatic nerve in the legs, and the ulnar nerve in the arm [22, 23]. Cranial neuropathy, which occurs infrequently in NSVN, may be seen in those with EGPA [24] and less often in GPA [25, 26].

NERVE LARGE ARTERIOLES VASCULITIS

Primary Systemic Vasculitis

Polyarteritis Nodosa

This multisystem disorder affects both small and medium-sized arteries and is the commonest type of primary vasculitic neuropathy so noted in up to 70% of patients [27, 28]. The skin and peripheral nervous system are the two organs most commonly involved (27). Renal arteritis, hepatitis B virus (HBV) infection and antigenemia, and visceral microaneurysms can all fall in the clinical spectrum of PAN [27, 29]. In contrast to AAV, PAN spares the lungs [30].

ANCA-Associated Vasculitis

Microscopic Polyangiitis

This AAV affects large arterioles and is associated with p-ANCA (or myeloperoxidase [MPO]-ANCA) in 50 to 70% of patients, and c-ANCA (or proteinase 3 [PR3]-ANCA) in 20 to 30% [31]. This disorder is differentiated from other AAV by the absence of granulomas. The incidence of MPA in Europe ranges from 3 to 10 per million [32] with a usual age at diagnosis of 60 to 70 years [33, 34]. Most patients have constitutional symptoms at the time

of diagnosis. Renal involvement, notably progressive glomerulonephritis occurs in 80% of patients, while peripheral neuropathy occurs in about 50% of patients [18, 35, 36]. Estimates of pulmonary involvement vary widely ranging from 25-92% [37, 38]. Alveolar hemorrhage caused by pulmonary capillaritis is the classic manifestation and is reported in up to 55% of patients [39, 40]. Skin lesions such as palpable purpura and gastrointestinal symptoms such as abdominal pain occur nearly 50% of the time (Greco 2015).

Eosinophilic Granulomatosis with Polyangiitis

This category of AAV affects small-sized vessels and large arterioles. The Lanham clinical diagnostic criteria required asthma, eosinophilia of greater than 1500/mm³, and vasculitis involving two or more non-pulmonary sites, not uncommonly in association with sinusitis [41]. The American College of Rheumatology 1990 Criteria requires 4 out of 6 of the following: asthma, eosinophilia, history of allergy, pulmonary infiltrates, paranasal sinus abnormalities, and extravascular eosinophils [42]. The disorder affects younger people with a mean age at diagnosis of 48 to 52 years [12, 43–46]. Neuropathy occurs in 60 to 70% of patients with infrequent cranial nerve involvement [12, 36, 41, 44, 45, 47, 48]. About 30 to 40% of patients display ANCA-seropositivity, typically p-ANCA [12, 41, 49]. ANCA-positive patients are more likely to have peripheral nerve involvement and glomerular nephritis whereas cardiomyopathy is more common in ANCA-negative patients [12, 44, 50].

Granulomatosis with Polyangiitis

Granulomatosis with polyangiitis primarily affects the lungs and kidneys [51–53], though the skin, heart and GI tract may also be involved [54]. The disease presents in two stages, first with localized granulomatous inflammation of the respiratory tracts resulting in nasal ulceration, nasoseptal perforation, sinusitis, conductive hearing loss and otitis media. The next stage is generalized vasculitis heralded by constitutional symptoms and vasculitic involvement of the upper respiratory tract, lungs, kidneys and eyes [18, 52]. Neuropathy occurs in approximately 25% of patients [55]. With cranial involvement in between 15% to 33% of patients with GPA [14, 25, 56, 57]. GPA has an estimated relapse rate of 50% [51, 58].

Secondary Systemic Vasculitis

Rheumatoid Vasculitis

Rheumatoid vasculitis (RV) typically affects small to medium-sized arteries, including smaller arterioles, capillaries and venules [59], and is typically a late manifestation of severe seropositive RA. Vasculitic neuropathy occurs in 40 to 50% of patients with RV and in about 10% of patients with RA [47, 60]. Smoking, vascular disease and severity of RA are risk factors for RV [61]. Despite aggressive treatment, mortality rates remain high at approximately 25% over 5 years [61]. Central fascicular fiber degeneration distal to the site of ischemia with multifocal fiber loss and axonal degeneration was found among more than 15,000 serial skip sections in tissue sections of the roots, lumbosacral plexus, fibular and tibial nerves at postmortem examination of a patient with RV and peripheral neuropathy [18]. In spite of necrotizing vasculitis of small arteries and large arterioles, there was no evidence

of ischemic nerve injury until the mid-sciatic vascular watershed zone, the latter of which is now regarded as the initial site of nerve infarction in many forms of vasculitic neuropathy.

Sjögren Syndrome

Estimates of peripheral nerve involvement in Sjögren syndrome vary from 2 to 64% [62] with presentation of trigeminal sensory neuropathy, distal sensorimotor neuropathy, small or large fiber sensory neuronopathy, autonomic neuropathy, and multiple mononeuropathy [47, 63, 64]. The latter neuropathy was encountered in 3 to 12% of patients as a manifestation of vasculitic neuropathy [47, 64]. Sjögren syndrome may be associated with either nerve large arteriole or microvasculitis with perivascular cellular invasion as the most common histological feature in one series [64].

Viral Infection

Certain viral infections which persist in the body for long periods of time, such as HBV, hepatitis C virus (HCV), human immunodeficiency virus (HIV), and Parvovirus B19, demonstrate good associations with vasculitis and vasculitic neuropathies [65–67]. Those with HBV infection who also go on to develop PAN typically do so within the first 9 months of the acute hepatitis [68]. Moreover, circulating HBV surface antigenemia, so noted in 10 to 50% of patients with PAN, does not distinguish the 1 to 5% who go on to develop PAN (69). Hepatitis is often undiagnosed prior to the onset of PAN when clinically latent. Although clinical symptoms may be similar, peripheral neuropathy was more common in HBV-related PAN than those without concomitant HBV infection, so noted by Pagnoux and colleagues [27] in 85% of patients with HBV-related PAN.

Chronic HCV infection is a determinant of cryoglobulinemic vasculitis (CV) [70], with up to 65% of patients with HCV-related CV developing clinically significant peripheral neuropathy. Affected patients present with palpable purpura, glomerulonephritis, leg ulcers, arthritis, and sicca syndrome. Tissue damage in CV results from complement-dependent immune complex mediated inflammation of small blood vessels [71] with 85% of patients manifesting overtly abnormal electrodiagnostic findings [72]. In one relatively large series of patients, CV neuropathy comprised of only 8% of 71 patients with cryoglobulinemic neuropathy [73]. Patients with HCV-associated PAN similarly also develop vasculitic neuropathy in the absence of cryoglobulinemia [74]. In contrast to HCV-associated CV, HCV-associated PAN patients had a higher incidence of constitutional symptoms, multiple mononeuropathy, livedo, hypertension and GI tract involvement [74].

Paraneoplastic Vasculitis

Paraneoplastic vasculitic neuropathy occurs in the setting of hematologic tumors, thymoma, and small cell lung cancer with lesions confined to the peripheral nerves and muscles in biopsy and postmortem tissue sections [75, 76]. Anti-Hu or serum antineuronal nuclear antigen-2 (ANNA-2) autoantibodies are associated with paraneoplastic vasculitic peripheral neuropathies [77]. In contrast to paraneoplastic vasculitis, solid tumors are more often associated with paraneoplastic vasculitic neuropathies than hematological malignancies [78]. Sensory ataxia and autonomic dysfunction may occur in patients who harbor anti-Hu antibodies.

Drug-Induced Vasculitis

Several drugs have recently been associated with vasculitic neuropathies. Minocycline, which is a tetracycline derivative used for acne vulgaris, has been reported to trigger a vasculitic neuropathy in several patients [79, 80]. The time course from time of initiation of the minocycline to development of peripheral nerve vasculitis is variable. Discontinuation of minocycline and initiation of corticosteroids and other immunosuppressant drugs results in improvement. Minocycline has interestingly also been associated with CNS vasculitis [81].

Cocaine has been implicated as a trigger in AAV [82]. Cocaine may actually spark a pseudovasculitis rather than the true vasculitis seen in systemic AAV [83]. Patients will have sinus involvement, a vasculitic purpuric rash, inflammatory arthritis and peripheral neuropathy. ANCA positivity may be c-ANCA or p-ANCA [82]. Corticosteroids and steroid sparing agents may be used.

Anti-programmed death 1 (PD-1) antibodies, such as pembrolizumab or nivolumab, are used in the treatment of solid-organ tumors and hematological cancers [84]. These immune checkpoint inhibitors have been associated with various autoimmune complications including two cases of vasculitic neuropathy [84, 85]. In addition to discontinuation of the antibody treatment, additional immunotherapy may be necessary [84].

MICROVASCULITIS

Non-Systemic Vasculitic Neuropathy

NSVN differs from SVN in its restriction to the nerves secondarily affecting muscle, the slow progression, and non-fatal outcome [47]. There are typically less severe constitutional symptoms or less markedly abnormal laboratory studies. Approximately one-third of patients report a weight loss and 10 to 13% note fever [9]. As a result of slow, progressive development of asymmetric and multifocal neurological deficits, there is often a longer delay, in some reports up to 14 years, to diagnosis than systemic vasculitic neuropathy [16, 17, 86, 87]. Overall, 45% have an asymmetric neuropathy, 33% multifocal neuropathy and 23% symmetric polyneuropathy [9]. Patients with NSVN typically present with pain and weakness that commences unilaterally and spreads to the contralateral side in 80 to 90% of patients. Twenty percent of patients will have no pain [9]. Affected patients classically manifest sensorimotor symptoms and signs, with 15% of patients presenting a sensory-predominant syndrome depending upon both the precise location and extent of the vasculitic lesion in the mixed nerve and selective involvement of sensory branches [18]. Continued monitoring is recommended for those with NSVN since 10% of affected patients may evolve into SVN. Most patients continue to be ambulatory and independent in activities of daily living [9]. Sugiura and colleagues [88] considered NSVN, noting the clinicopathologic similarity to MPA, in spite of restriction of relapses to the PNS, the absence of ANCA-seropositivity, and overall improved prognosis of the former. Takahashi and colleagues, however, demonstrated a distinct pathogenesis in NSVN and MPA [89]. In both ANCA-positive and ANCA-negative MPA, neutrophils attach to vascular endothelial cells, whereas complement plays more integral role in NSVN with C3d deposition in epineurial small vessels. The antigens most often identified in the inflammatory lymphocytic infiltrates in NSVN include CD52, BAFF,

and CD49d which were expressed in the epineurial, perivascular and intramural lymphocytes in all 20 treatment-naïve sural nerve biopsies in one series [90].

Diabetic Lumbosacral Radiculoplexus Neuropathy

Dyck and coworkers [91] described monophasic severe lower leg pain and weakness that commenced unilaterally, with delayed involvement of the other leg in an asymmetrical pattern affecting both the proximal and distal lower extremities in middle to later age type 2 diabetics with relatively good glycemic control. The onset of pain and weakness is often heralded by significant weight loss, a median of 30 pounds in the Dyck study [91]. There is generally a lack of correlation between developing DLRPN and a greater duration or severity of diabetes mellitus, as opposed to cases of typical diabetic polyneuropathy. Sharp, lancinating allodynic pain and burning sensations along the legs are typical presenting features. Sensory impairments become overshadowed by leg weakness, which is the most disabling feature, prompting use of ambulatory aids including wheelchairs in one-half of patients [91]. The non-diabetic form "LRPN" has an identical presentation of monophasic severe lower leg pain and weakness [92, 93]. Unlike other forms of vasculitic neuropathy, multiple leg and thigh nerves, lumbosacral plexus and nerve roots are affected. Electrodiagnostic studies reveal active axonal features and acute spontaneous activity in multiple proximal and distal lower leg muscles and in lumbosacral paraspinal muscles, and motor unit potential changes consistent with a radiculoplexus (involving root, plexus and peripheral nerve) neuropathy as the term LRPN implies. Autonomic nervous system (ANS) involvement occurs in approximately one-half of patients. There may be associated thoracic radiculopathy and mononeuropathy of the arms, and less commonly cervical radiculoplexus neuropathy [91]. An etiopathogenesis attributed to microvasculitis-induced ischemic injury was postulated in a series of 33 prospectively studied patients with DLRPN [91] in whom biopsy of a distal cutaneous nerve revealed neovascularization, injury neuroma, perineurial thickening, multifocal fiber loss and abnormal amounts of inflammation, one-half of the biopsied nerves showed findings diagnostic or suggestive of microvasculitis. Further in support of a vasculitic ischemic etiopathogenesis, was the finding of necrotizing arteritis in biopsy tissue of the superficial fibular cutaneous nerve of a patient with clinically apparent DLRPN [94] in whom postmortem examination also showed epineurial perivascular inflammation of the femoral nerve, lumbar plexus and roots. Although spontaneous improvement is expected, recovery is often incomplete with foot drop being the most common long-term sequela.

Diabetic Cervical Radiculoplexus Neuropathy

Massie and colleagues [95] reported a series of 85 patients with DCRPN, most of whom were type 2 diabetics, with a mean age of 62 years. The commonest presenting symptoms were pain noted in 69 (81%), and numbness in 56 (66%) of patients, which were overshadowed by weakness noted in all but one patient. In contrast to DLRPN, the presentation was more acute and clinical deficits peaked in the first week. Moreover, unlike brachial plexus neuritis, which typically manifests upper trunk involvement, the upper, middle and lower plexuses are equally affected in DCRPN, with about 30% of patients demonstrating pan-plexus involvement. Electrodiagnostic studies showed axonal neuropathy in all 80 patients studied, with evidence of paraspinal denervation in 32%, with abnormal ANS testing (evaluating cardiovagal, cardioadrenergic, and post-ganglionic sudomotor

function) in 96%, and abnormal quantitative sensory testing in 77%. Altogether, 44 (52%) patients had one or more additional body regions affected including 30 contralateral cervical, 20 lumbosacral, and 16 thoracic regions. Evidence of ischemic nerve injury was the predominant feature in cutaneous nerve biopsy tissues, within which epineurial perivascular inflammation was seen in all 22 specimens, microvasculitis in 5 (23%), multifocal nerve fiber loss in 15 (68%) and inflammation involving vessel walls in 14 (64%). The pathological findings were essentially the same as found in diabetic and non-diabetic LRPN. Given the clinicopathologic similarity to DLRPN these two disorders are categorized together in the spectrum of diabetic radiculoplexus neuropathy.

Painless Diabetic Motor Neuropathy

Garces-Sanchez and colleagues [96] described painless diabetic motor and lower limb-predominant neuropathy among 23 patients of mean age 62 years, 22 (96%) of whom had type 2 diabetes. Similar to those with DLRPN and LRPN, chronic diabetic complications were uncommon and weight loss was typical. Most patients had gradual onset of bilateral foot-drop that spread to the proximal legs and occasionally the arms. However, in comparison to DLRPN, the neurological deficits of those with PDMN were more severe with over one-half of patients confined to a wheelchair by the time of presentation. Despite the motor-predominant presentation, most had sensory symptoms, less than one-half of affected patients had ANS involvement, and significantly more patients had arm involvement compared to patients with DLRPN. Electrodiagnostic studies showed pan-modality sensory loss, ANS abnormalities, and axonal polyradiculopathy with lumbosacral paraspinal muscle denervation. Cutaneous nerve biopsy findings showed ischemic injury like other radiculoplexus neuropathies, with evidence of epineurial perivascular inflammation in all 23, with vessel wall invasion in 15 (65%) and microvasculitis in 4 (13%) of nerves. Given the absence of ischemic injury and microvasculitis in nerve biopsy specimens of analogous patients with diabetic chronic inflammatory demyelinating polyradiculopathy (CIDP), the authors [96] concluded that the patients with PDMN were best classified as a form of radiculoplexus neuropathy rather than a form of diabetic CIDP.

DIAGNOSIS

There is general agreement on four principles in the diagnosis of vasculitis which are applicable to peripheral nerve vasculitis [1]. First, vasculitis is a potentially serious disorder with a propensity for permanent disability owing to tissue ischemia and infarction. Therefore, prompt recognition of the typical neurologic manifestations of peripheral nerve vasculitis is key to placing it high up in the differential etiologic diagnosis of peripheral neuropathy. Second, undiagnosed and therefore untreated, there is a likelihood of excess morbidity. Third, a favorable response to an empiric course of immunosuppressive and immunomodulating therapy should never be considered a substitute for the absolute proof of the laboratory diagnosis of vasculitis. Fourth, histopathologic confirmation of vasculitis is essential for the accurate diagnosis of peripheral nerve vasculitis, such as by analysis of nerve and muscle biopsy tissue when PNS involvement is postulated.

All patients with peripheral neuropathy due to suspected primary or secondary peripheral nerve vasculitis should be thoroughly evaluated for systemic involvement including disease-specific serological studies guided by the clinical presentation and postulated etiologic diagnosis to avoid excessive cost and spurious results. ANCA serology is mandatory in the evaluation of suspected SVN. ANCA are a family of autoantibodies that react with proteins that are expressed in cytoplasmic granules of polymorphonuclear cells. The presumptive ANCA autoimmune response, which is regarded as a multifactorial process that includes genetic predisposition, environmental factors, an initiating antigen, and altered T-cell regulation, primes neutrophils by binding to certain antigens expressed on their surface, and ANCA-activated neutrophils contribute to an inflammatory amplification loop that recruits other effector cells leading to granuloma formation [97]. However, there are significant differences in sensitivity, specificity and predictive value among commercially-available ANCA enzyme-linked immunosorbent assay (ELISA) kits. An International Consensus Statement [98, 99] suggested guidelines for ANCA testing recommending screening by standard immunofluorescence tests (IFT) and mandatory antigen-specific ELISA for positive IFT tests. The three major IFT patterns [100] including, granular cytoplasmic neutrophil fluorescence with central interlobular accentuation, perinuclear neutrophil staining often with nuclear extension, and another comprising a mix of cytoplasmic and perinuclear fluorescence, correlate respectively with C-ANCA, P-ANCA, and atypical ANCA with multiple specificities. C-ANCA-seropositivity typically occurs in patients with active generalized GPA, whereas P-ANCA occurs in patients with MPA and EGPA; ANCA with multiple antigen specificities often occurs in the absence of vasculitis. Autoantibodies with specificity for myeloperoxidase are referred to as MPO-ANCA and those against proteinase-3 are PR3-ANCA. The c-ANCA pattern is in most cases caused by antibodies to PR3. P-ANCA pattern is less specific, but MPO is an antigen associated with this pattern [101].

Biomarkers are emerging as potentially useful predictors of disease activity including neurofilament light chain and VEGF [102, 103]. There are published consensus recommendations for the laboratory investigation of suspected vasculitic neuropathy (Table 2) [4].

Electrodiagnostic studies are useful in the initial investigation of vasculitis because they can identify areas of asymptomatic involvement, sites for muscle and nerve biopsy, and when combined with the clinical and laboratory evaluation, support the specific neuropathic syndrome with a high degree of certainty. A wide sampling of nerves and muscles should be examined, both distal and proximal, with side-to-side comparisons. Most patients with peripheral nerve vasculitis will have multiple, acute or subacute, axonal mononeuropathies. Over time, a distal symmetric or asymmetric pattern due to the confluent nature of additional superimposed vasculitic lesions may be appreciated.

Table 2. Recommended laboratory studies in suspected vasculitic neuropathy

<i>Initial studies:</i> Complete blood count with differential (for eosinophil count), comprehensive metabolic panel, urinalysis, erythrocyte sedimentation rate, C-reactive protein, anti-neutrophil cytoplasmic antibodies (autoantibodies to proteinase-3 and myeloperoxidase), serum protein electrophoresis, complement levels (including C3, C4, and total), glycosylated hemoglobin, or 2 hour glucose tolerance test, hepatitis B surface antigen, hepatitis C antibodies, cryoglobulins, chest x-ray, and urinalysis.
<i>Additional studies:</i> Extractable nuclear antigen profile (including SSA/SSB antibodies), double-stranded DNA antibodies, rheumatoid factor, cyclic citrullinated peptide antibodies, angiotensin converting enzyme, human immunodeficiency virus antibodies, paraneoplastic autoantibodies, salivary gland biopsy, and malignancy imaging.

In patients suspected to have a vasculitic neuropathy, open biopsy of a cutaneous sensory nerve and companion muscle tissue are indispensable in the evaluation of primary and secondary peripheral nerve vasculitis. However, they should only be performed at major neuromuscular centers to assure that all necessary specimens are obtained, and they are processed correctly for light microscopy of cryostat- and paraffin-stained hematoxylin and eosin (H&E) sections, supplemented by plastic embedded, 1-mm semithin sections, and teased nerve fiber analysis. Such studies generally show evidence of axonopathy with Wallerian degeneration due to nerve ischemia and vasculitis supported by the presence of myelin ovoids, myelin debris, macrophage recruitment along the course of degenerated fibers, marked fascicular depletion of myelinated and unmyelinated nerve fibers, and endoneurial fibrosis. Immunocytochemical studies including lymphocyte cell marker analysis and complement immunofluorescence can be performed to identify activated components of the cell-mediated and humoral immune system. Cutaneous nerve biopsy is generally unnecessary in those with obvious DLRPN, LRPN, DCRPN and new-onset of multifocal neuropathy and known systemic vasculitis. However, cutaneous nerve biopsy may be useful in cases of prolonged DLRPN, LRPN and DCRPN where the disease course is protracted a year or more, and the treating physician needs to know if there is active microvasculitis. It may also be beneficial in cases with atypical clinical, electrophysiological, and magnetic resonance imaging (MRI) features, to accurately confirm the diagnosis. The sural nerve and superficial fibular sensory nerves are the commonest nerves studied in the legs, likewise the superficial radial sensory nerve for the evaluation of vasculitis in the upper limbs [2]. The addition of soleus or peroneus brevis muscle from the same incision as the sural and superficial fibular sensory nerves increased the yield of vasculitis by 15 to 25%, to an estimated overall sensitivity of 50 to 60% in several series [2, 104, 105]. Deprez and coworkers [106] studied clinicopathologic correlations in 355 retrospective patients with peripheral neuropathies noting a greater yield of nerve biopsy in those with multifocal and asymmetrical patterns, and a clinical onset-to-biopsy interval of less than six months. Chalk and colleagues [107] studied the diagnostic usefulness of ANCA serology in 166 consecutive patients, noting ANCA-seropositivity in four of six patients with vasculitic neuropathy; however, false-positive results limits its diagnostic usefulness in peripheral neuropathy.

TREATMENT

Treatment of vasculitic neuropathy can be divided into 3 broad categories including treatment of non-infectious nerve large arteriole vasculitis (including primary SVN and secondary SVN); treatment of infectious nerve large arteriole vasculitis, and treatment of NSVN and other microvasculitides. Treatment of SVN should be initiated immediately as the one-year mortality rate approaches 90% in untreated patients with GPA and PAN compared to 12 to 20% among those promptly treated [4, 108]. The usual approach to treatment is induction of remission followed by long-term maintenance therapy which is continued for 18 to 24 months [109–113]. Corticosteroids are standard initial therapy for both SVN and NSVN. The addition of cyclophosphamide is usually necessary in those with MPA and GPA, and in others with NSVN who progress while on corticosteroids alone. A good tool for assessing response to treatment is the Neuropathy Impairment Score (NIS) because it

combines weakness, reflex changes and sensory loss, as well as a standard neurological examination and follow up electrodiagnostic studies. The 1996 and 2009 revised Five-Factor Score (FFS) can help prognosticate in patients with PAN, MPA, EGPA, and GPA [114, 115]. Four factors are each allocated one point: renal insufficiency, cardiomyopathy, severe gastrointestinal manifestations, and age >65. ENT involvement, the fifth factor, is considered protective, so if absent, is allocated one point. The fifth factor is only used for EGPA and GPA. Five-year mortality rates for scores of 0, 1, and >2 were 9%, 21%, and 40% respectively. Neuropathy itself does not affect survival. If new neurological deficits develop, treatment should be escalated [3, 4, 7, 27, 116–118]. The starting dose of prednisone is 1.0 mg/kg/day and in severe cases is administered intravenously as methylprednisolone at a dose of 1000 mg for 3 to 5 days, followed by oral prednisone [119]. Oral prednisone is slowly tapered by 5 to 10 mg every few weeks after one to two months depending on the patient's response and severity of the disease [7, 120]. The erythrocyte sedimentation rate (ESR) and other markers of acute inflammation [2], including ANCA levels in those with AAV [121], should be monitored at baseline and with treatment. Maximal improvement occurs in 6 to 24 months after initiation of corticosteroids due to the slow pace of axonal regeneration. When needed, cyclophosphamide can be administered as an intravenous pulsed dose or as daily oral therapy with anticipated equal efficacy, however oral cyclophosphamide is associated with a higher incidence of side effects [122–127]. Intravenous pulse therapy is associated with higher relapse rate upon follow up [127]. Once remission is achieved with cyclophosphamide and prednisone, methotrexate or azathioprine can be substituted for the cyclophosphamide [128–130]. Patients with refractory disease despite treatment with cyclophosphamide and corticosteroids can be treated effectively with rituximab [4, 131–133]. Newer treatment protocols that combine rituximab, intravenous cyclophosphamide and oral prednisone in AAV have recently been published [134]. There is continued research to determine the best regimen for AAV patients [135] with rituximab emerging as likely first line therapy [136]. Other options include intravenous immune globulin (IVIg), plasma exchange, and mycophenolate mofetil.

Azathioprine is used as alternative maintenance therapy to cyclophosphamide in those with SVN and NSVN especially those in whom remission has been induced with cyclophosphamide. The timing of discontinuation of azathioprine does not clearly influence the relapse rate in AAV [137]. Azathioprine should not be added to corticosteroids to induce remission in AAV as it does not improve remission rates, lower the risk of relapse, or spare steroids [138]. Methotrexate can be used with corticosteroids for induction of remission in mild, non-life-threatening AAV and in patients with SVN and typical NSVN in lieu of azathioprine for remission maintenance following cyclophosphamide induction [7]. Methotrexate should be continued for 18 to 24 months prior to attempted tapering. Methotrexate has been found to be non-inferior to cyclophosphamide in remission maintenance [139]. IVIG was found to be effective in patients with diverse forms of vasculitic neuropathy and in those with AAV refractory to standard therapy [140–143].

The chimeric anti-CD20 monoclonal immunoglobulin rituximab is first-line therapy for induction of remission in patients with GPA and MPA instead of cyclophosphamide [136]. It is also effective in patients with CV and RV [144–150]. Nearly 90% of patients with treatment-refractory AAV improved following rituximab treatment in uncontrolled series [72, 136]. Plasma exchange is an option in patients with fulminant vasculitis and significant organ

impairment, as well as, in HBV-associated PAN, HCV-associated CV, and HIV-associated systemic vasculitis [151–156].

For most HCV genotypes a combination of interferon-free antiviral drugs (sofosbuvir and ribavirin), immunosuppressive drugs, with or without plasmapheresis should be used [157, 158]. If the patient has HCV genotype 6, direct-acting antiviral drugs, such as pegylated interferon injections are used [158]. Rituximab may be more effective in patients with severe cryoglobulinemic vasculitis [71, 72, 146, 159]. For non-cytomegalovirus-related HIV vasculitis, treatment is similar to HBV-associated PAN using antiviral therapy and plasma exchange, although in clinical practice most use corticosteroids [28, 160]. The current recommendation is to treat HBV-associated PAN with lamivudine, corticosteroids and in severe cases, plasma exchange [161, 162]. Prolonged corticosteroid treatment should be avoided as it favors viral replication (163). The French Vasculitis Study Group [65, 155] treatment protocol for HBV-related PAN that included antiviral agents, therapeutic plasma exchange to remove circulating immune complexes followed by two weeks of corticosteroids to treat the severe symptoms, induced complete remission in 80 to 90% of patients.

The 2010 Peripheral Nerve Society published guidelines for the immunosuppressive therapy of classic NSVN [4] Since that time, most experts now recommend initiation of combination therapy (corticosteroids with cyclophosphamide, methotrexate, or rituximab) [9]. Azathioprine should not be used as induction therapy but can be used as maintenance therapy. Rituximab can be also be used as maintenance therapy [9].

Patients with progressive symptoms early in the course of DLRPN or LRPN are candidates for immunotherapy [166]. One prospective, randomized, double-blind, multicenter- controlled trial employing intravenous methylprednisolone in patients with DLRPN found improvements in indices of pain but not neurological function [167]. However, a concern is that patients may have been enrolled and treated too late in the disease course to affect impairment, and may not reflect a true degree of benefit of early treatment in a monophasic inflammatory disorder. One open uncontrolled study employing intravenous methylprednisolone in patients with clinically deteriorating LRPN, showed improvement in NIS commensurate with clinical improvement in all patients [168, 169]. While case series of patients [169–171] with radiculoplexus neuropathies suggest improvement in pain and strength with IVIg, there have been no randomized trials of plasma exchange in DLRPN or LRPN. One case series of five patients with DLRPN treated with plasma exchange demonstrated improvement [172]. Considering that DLRPN and LRPN are subtypes of NSVN, a similar treatment regimen for patients with LRPN should be undertaken.

Pain control is of utmost importance in vasculitic neuropathy and the usual medications employed include tricyclic antidepressants, pregabalin, gabapentin, serotonin-norepinephrine reuptake inhibitors, valproate, carbamazepine, tramadol, topical lidocaine, topical capsaicin, and narcotics [173]. Continued pain without progressive neurologic deficits is not an indication for high-dose corticosteroids.

CONCLUSION

Peripheral nerve vasculitis is commonly encountered in patients with primary systemic vasculitis, but may also be secondary to viral infections, malignancy, and concomitant

connective tissue disease. All peripheral nerve vasculitic neuropathies involve small blood vessels and classification is based upon separation into nerve large arteriole vasculitis (which typically has fibrinoid necrosis of the involved vessel) and nerve microvasculitis (which typically does not have fibrinoid necrosis). Primary and secondary systemic vasculitic neuropathies are forms of nerve large arteriole vasculitis. Non-systemic vasculitic neuropathy accounts for up to 30% of all vasculitic neuropathies. Altogether, NSVN, as well as some forms of secondary systemic vasculitic, and the radiculoplexus neuropathies including DLRPN, LRPN, DCRPN, and PDMN, the latter of which may be considered localized forms of vasculitic neuropathy, will likely be associated with peripheral nerve microvasculitis. Treatment employing corticosteroids, systemic immunosuppressive agents, and immune modulation with plasma exchange and intravenous immune globulin, all suitable options in patients with severe and progressive neurological deterioration, especially to reduce excess morbidity and mortality.

Chapter 223

CENTRAL NERVOUS SYSTEM VASCULITIS DUE TO DRUG ABUSE

David S. Younger*, MD, MPH, MS

ABSTRACT

Illicit drug abuse is a common differential diagnosis of acquired central nervous system vasculitis even though there are only a handful of histopathologically confirmed patients in the literature from among the many potential classes of abused drugs traditionally implicated in this disease. Since publication of the first edition of this chapter, there has been increasing interest in the acute neurotoxicity associated with adulterants. This chapter considers the major classes of illicit drugs in those with and without human immunodeficiency virus type 1 infection and acquired immune deficiency syndrome.

EPIDEMIOLOGY

Drug abuse is a significant public health burden [1]. Globally, it has been estimated that 3.5 to 5.7% of the population age 15 to 64 years, or approximately 250 million persons consumed an illicit drug once in the past year [2]. Taking into account the pattern of drug use, an estimated 16 to 38 million persons are considered regular or frequent users due to psychic and physical drug dependence or addiction, and an additional 11 to 21 million inject drugs [1]. This wide range of estimations are due to lack of reliable epidemiological data on specific

drug abuse, all of which can be cause injury to the central nervous system (CNS) including opiates, heroin, cocaine, amphetamine, and methamphetamine.

The misuse and abuse of drugs in the United States (US) has reached epidemic proportion, and extends to both adolescents and adults. Although individuals with a drug addiction may favor one or another class of illicit drugs, most perform polysubstance abuse. Such a trend was discerned in an analysis of accidental overdose deaths in New York City between 1990 and 1998 due to heroin, cocaine and alcohol. That combination accounted for 97.6% of all deaths, 57% of which were attributed to two or more of these drugs in combination [3] among accidental drug overdose deaths attributed to one drug alone, those positive for cocaine only were the commonest representing 1.93 per 100,000 person-years. In developing countries, illicit use, non-pharmacy sales, counterfeit drugs, and self-treatment complicate the public health concern surrounding substance abuse.

CLASSIFICATION AND NOSOLOGY

The most widely used classification and nosology for the vasculitides is the 2012 Revised International Chapel Hill Consensus Conference [4] Nomenclature. There is a recent review of CNS vasculitis [5].

BLOOD BRAIN BARRIER

The past decade has witnessed extraordinary progress in our understanding of the blood brain barrier (BBB) [6], and progress in its understanding will likely afford new insights into our understanding of cerebral vasculitis. The neurovascular unit (NVU) of the BBB is comprised of capillary endothelial cells, pericytes, smooth muscle cells, astrocytes, and neuronal terminals, and white blood cells in the extended NVU.

Each of the components expresses a wide variety of receptors, ion channels, and transporters that reside in proximity to one another allowing for the dynamic modulation of blood flow, metabolism, and electrophysiologic regulation [7]. Many of the influx and efflux mechanisms of the BBB are present early in the developing brain, encoded by genes at much higher levels than in the adult [8]. The disruption of tight and adherens junctions, enzymatic degradation of the capillary basement membrane, or both, leads to disruption of tight junctions (TJ), altered expression and function of membrane transporters or enzymes, increased passage of inflammatory cells across the BBB from the blood to CNS, and dysfunction of astrocytes and other components [7]. This leads to aberrant angiogenesis and neuroinflammation with concomitant vasogenic edema, accumulation of toxic substances in the brain interstitial fluid, oxidative stress, and impaired ion and water homeostasis.

AMPHETAMINE AND RELATED AGENTS

Background

The earliest reports of misuse of amphetamine sulfate were in late 1930 when students to avoid sleep during examination periods [9] used it. This was followed by reports of death by those who ingested the drug repeatedly as a stimulant for the same purpose [10], in a suicide attempt that resulted in a fatal intracerebral hemorrhage [11], or accidentally, when dexamphetamine and phenelzine were fatally ingested together decades later [12].

During the Second World War, amphetamine and methamphetamine was used clinically and illicitly but its abuse soared in San Francisco after 1962 where it was illegally produced and distributed [13].

In 2009, the United Nations Office on Drugs and Crime (UNODC) estimated that 16 to 51 million persons between the age of 15 and 64 years consumed amphetamine drugs, with more than half using methamphetamine [14], exceeding the combined consumption of all other drugs of abuse except cannabis [15].

Neuropharmacology

The neuropharmacology of amphetamine, methamphetamine, and their derivatives has been recently reviewed [16, 17]. Such drugs agents comprise a large spectrum of agents [18] available in powder, capsule, tablet, and injectable fluid form that can be swallowed, snorted or taken intra-nasally, smoked or injected with highly variable purity and dosage equivalence. Their potent effects, which include elevation of blood pressure, pulse rate, and increased level of alertness, sometimes in association with insomnia, excitability, panic attacks, and aggressive behavior, can also be associated with seizure and stroke.

The effects of methamphetamine are distributed throughout the brain [19]. Ecstasy refers to the different hallucinogenic amphetamine derivatives that contain 3, 4-methylenedioxymethamphetamine (MDMA) and 3, 4-methylenedioxyethylamphetamine (MDE) as the main components [20]. Ecstasy alters brain serotonin concentrations, and postsynaptic 5-HT₂ receptors play a role in the regulation of brain microvessels.

The CNS toxic effects are mitigated through blocking of the reuptake of dopamine (DA) and stimulation of the release of DA and norepinephrine (NE), as well as, possible involvement upon serotonergic and endogenous opiate system. There can be DA receptor desensitization with marked reduction of DA transporters and drug levels, as well as other dopaminergic axonal markers. The neurotoxic effects of methamphetamine in particular, are believed to be mediated in addition by multiple additional mechanisms including generation of free radicals, nitric oxide, excitotoxicity, mitochondrial dysfunction, apoptosis, and the induction of immediate early inflammatory genes and transcription factors.

Methamphetamine is the most potent amphetamine and the most commonly abused. All forms of amphetamine administration increase the risk of stroke that may be ischemic, hemorrhagic and intraparenchymal [21], and which may be up to four-fold that of nonusers [22], surpassing the rate of hemorrhagic stroke caused by cocaine use with odds ratios respectively of 4.95 versus 2.33 [23]. Still, amphetamines and methamphetamine are the

second commonest cause of all strokes after cocaine, occurring largely in persons younger than 45 years.

Clinicopathological Spectrum of Amphetamine-Related Cerebral Vasculitis

Excluded Literature Patients

Amphetamine was not the definite causative agent of purported cerebral vasculitis in the patient described by Kessler and colleagues [24] with acute intracerebral hemorrhage, or in the patient reported by Bostwick [25] with ischemic stroke in two multi-drug abusers of heroin, cocaine, and amphetamine with beading of small tributaries of the middle cerebral artery (MCA) [24] or occlusion of the right internal carotid artery (ICA) [25]. Postmortem examination in the first patient [24] showed occasional intramural mononuclear and polymorphonuclear cellular infiltration of small leptomeningeal arteries, while histopathology of the second patient [25] was not provided.

Detailed histopathology was lacking in the patient described by Olsen [26] as “vasculitis and cerebritis” as the cause for subarachnoid hemorrhage in a drug abuser who injected Methedrine and soon afterward lapsed into a fatal coma. Cerebral angiography that demonstrated typical features of vasculitis in conjunction with a skin biopsy that revealed granular deposits of IgM and C3 component around the lumina of small vessels of the upper dermis consistent with immune complex disease were the supportive features of cerebral vasculitis in a patient who ingested methamphetamine and later developed headache, nausea and vomiting heralding subarachnoid, without other confirmatory histopathology [27].

Corroborative histopathology was not sought in 10 other often cited patients [28-30] including a young man with presumed cerebral vasculitis attributed to chronic exposure to methylphenidate for 7 years beginning at age 5 to treat hyperactivity and attention deficit disorder. At age 18 years, he was diagnosed with right hemidystonia, whereupon MRI of the brain disclosed chronic infarction in the head of the right caudate, putamen, pallidum, internal capsule and temporal lobe, with occlusion of the left anterior cerebral artery (ACA) and posterior branch of the left MCA on cerebral angiography [28].

Likewise corroborative histopathology was not sought in 8 patients described by Buxton and McConachie [29] who developed presumed intracranial vasculitis as cause for subsequent lobar (5 patients), subarachnoid (2 patients) or brainstem hemorrhage (1 patient) following oral or inhaled amphetamine in whom cerebral angiography showed beading in the one patient with subarachnoid hemorrhage, and normal in 6 others.

Moriya and Hashimoto [31], Shibata and coworkers [32], and Delaney and colleagues [33] each described a patient with fatal intracranial hemorrhages following intravenous injection of amphetamine (2 patients) alone [31, 32] or intranasal injection of methamphetamine (1 patient) [33]. Postmortem examination in one patient [31] did not reveal vascular lesions, while that of another patient [32], with evidence of necrosis of blood vessels walls along named cerebral arteries, failed to reveal cellular infiltration of vessels walls. Detailed gross and microscopic examination of the cerebral vessels in another patient [33] showed no evidence of cerebral vasculitis.

Moreover, there was no mention of vasculitic lesions at postmortem examination of the CNS among 13 patients with purported vasculitis following fatal intravenous injection (1 patient) [34] oral ingestion of methamphetamine (6 patients) [35] or amphetamine sulfate (1 patient) [11], oral ingestion of combination dexamphetamine and phenelzine (1 patient) [12]. There was no evidence of postmortem or brain biopsy studies to investigate the possibility of cerebral vasculitis among 4 other often cited patients [36], 1 of whom was fatally injected with intravenous methamphetamine leading to cerebellar and brainstem hemorrhage; or in 3 other patients who survived ischemic infarction (2 patients) or lobar hemorrhage (1 patient) associated with inhaled (1 patient) or an unknown mode of administered of methamphetamine ingestion.

Cerebral vasculitis was not mentioned in a recent series of 30 patients, one third each of whom carried the diagnosis of ischemic stroke, intracerebral hemorrhage, or subarachnoid hemorrhage [37]. Nor were the postmortem findings of multiple large intracerebral vessels occlusions attributed to cerebral vasculitis in a patient with a fatal stroke, and attributed instead to accelerated atherosclerosis. Histopathology was not sought in two other fatal strokes or a patient with fatal subarachnoid hemorrhage [37].

Pathologically-Verified Literature Patients

Cerebral vasculitis due to amphetamine, methamphetamine and related agents is exceedingly rare with only 3 histopathologically studied patients in the literature [38, 27]. This is surprising given the number of substances that could cause this disorder if there was a true association. Citron and colleagues [38] in a highly publicized report of 14 Los Angeles multidrug abusers demonstrated amphetamine-related multi-organ arteritis including the CNS. The drug closest to a common denominator was methamphetamine using intravenously by all but two patients and exclusively by one. Acute vessel lesions of fibrinoid necrosis of the media and intima with infiltration by polymorphonuclear cells, eosinophils, lymphocytes and histiocytes, was followed by vascular elastic and vascular smooth muscle destruction resulting in lesions considered typical for polyarteritis nodosa (PAN). Two patients one abbreviated D.G. and the other E.V., who injected methamphetamine via intravenous injection had arterial lesions in cerebral and cerebellar (D.G.) and brainstem pontine vessels (D.G. and E.V.), however detailed histopathologic descriptions were not provided. Their report was followed by correspondence by Gocke and Christian [39] who contended that exposure to the Australia antigen of hepatitis B antigen was likely in their cohort [38] conceivably associated with circulating immune complexes and complement activation as had recently been described [40, 41]. The authors [42] responded that no more than 30% of sera from drug abuse patients ultimately tested positive for the Australia antigen. Those with antigen-positive sera who had used drugs others than methamphetamine had no evidence of angiitis when studied angiographically.

Baden [43] wrote that he had not observed a causal relation between drug abuse and necrotizing arteritis at the Office of Chief Medical Examiner of New York City for the past one-half century among thousands of autopsied drug abusers. Further, 14 cases were claimed documentation for angiitis was presented in only 4 patients but no substantiation for the diagnosis was given in the remainder except that 5 were asymptomatic, and 5 had a variety of nonspecific systemic signs and symptoms. Citron and Peters [42] responded that evidence of aneurysms so noted in 13 patients, was in their opinion ample evidence of arteritis.

Almost two decades later, cerebral vasculitis was demonstrated in a dubious report [27] of a three-week postpartum woman who took her first over-the-counter Dexatrim diet pill in many months containing phenylpropanolamine, without a history of amphetamine abuse. This was followed 90 minutes later by sudden headache, nausea vomiting and detection of subarachnoid blood on CT neuroimaging and a frontal lobe hematoma. Bilateral carotid angiography demonstrated diffuse segmental narrowing and dilatation of small, medium and large vessels and branches of the anterior and posterior circulation. Evacuation and histopathologic analysis of the hematoma was performed showing necrotizing vasculitis of small arteries and veins with infiltration of polymorphonuclear leukocytes particularly prominent in the intima with fragmentation of the elastic lamina and areas of vessel occlusion. It was unclear whether the findings were related to primary or drug-related CNS vasculitis. However, treatment with cyclophosphamide for 6 months was associated with almost complete resolution of cerebral angiographic abnormalities.

Etiopathogenic Mechanisms

After the report of Citron and colleagues [38], Rumbaugh and colleagues [44] described the cerebral vascular changes due to methamphetamine abuse in five rhesus monkeys given amphetamine in dose ranges used by human addicts. Two of the five monkeys developed generalized arterial spasm during a two-week period following intravenous injection. Three of the five animals demonstrated decreased caliber of named cerebral artery branches and flow of the contrast agent with normalization one day later while two others showed marked general decrease in small branches and large named vessels that improved in one animal and progressed in another. Histopathologic changes at postmortem examination included microaneurysmal enlargement of arteriolar segments, mononuclear perivascular cuffing of small arterioles, parenchymal necrosis, petechial hemorrhages, and swelling of brain tissue, with most of the hemorrhagic lesions centered on small-size arteriolar and capillary vessels. Although reminiscent of the clinical and histopathologic findings of Citron and colleagues [38], necrotizing arteritis and transmural inflammation were lacking. Five years later, Rumbaugh and coworkers [45] subjected monkeys to short-duration (2 weeks) (5 animals), medium-duration (1 month) (3 monkeys), and long duration (one year) (3 monkeys) of thrice weekly (1.5 mg/kg body weight) intravenous amphetamine and related agents including methamphetamine, secobarbital, methylphenidate, and placebo, with performance of cerebral angiography and documentation of the resulting histopathology. Their studies showed relatively severe vascular injury and brain damage from intravenous methamphetamine that included occlusions and slow blood flow in small cerebral vessels respectively in two each of the five monkeys in the long-term administered drug, and in three each of those given drug for intermediate and short durations, with some animals and controls unaffected. There was less injury caused by secobarbital and methylphenidate. Further, the possibility of vascular spasm due to subarachnoid blood was excluded by lack of blood at postmortem examination in the subarachnoid space in any of the animals.

COCAINE

Background

A classic review of cocaine and stroke describes its abuse potential [46]. Cocaine, which is derived from the leaves of the *Erythroxylum coca* plant found primarily in the eastern mountains of Peru, Ecuador, and Bolivia, is available for abuse as cocaine hydrochloride, a water-soluble white salt in crystal, granular, and white powder that can be sniffed and “snorted” intranasal or injected parenterally [3]. The “free base” alkaloid form is known as “crack” [16] derives its name from the cracking sound that occurs after dissolution of the hydrochloride salt in water, heated, and mixed with ammonia without or without baking soda. This chemical reaction converts cocaine hydrochloride to a volatile form of the drug, almost pure cocaine. Street cocaine or the non-crack form is highly variable in purity, and often cut with various agents [47]. The alkaloid free-based form, which is inhaled or smoked, is accompanied by higher blood concentrations and more pronounced euphoria.

When smoked as free-base, it is absorbed into the pulmonary circulation and transmitted to the brain in <10 seconds. After appearance in the bloodstream, cocaine is rapidly hydrolyzed to benzoylecgonine [48], which can be accurately tested in the urine; however, levels may persist for up to 27 to 36 hours depending upon the route of administration and host cholinesterase activity [49-51]. In recent years, with increasing availability and purity, and a drop in the price of cocaine from the early 1970s, new cohorts from all socioeconomic backgrounds and age groups have been attracted to this highly addictive drug, and use has continued to expand on a year-by-year basis.

Neuropharmacology

Cocaine is a highly potent central nervous system (CNS) stimulant that rapidly crosses the BBB due to its highly lipophilic properties and is widely distributed through the brain with its major metabolites binding at receptors with varying affinities at presynaptic sites, stimulating the release of dopamine (DA) from synaptic vesicles and blocking DA reuptake resulting in enhanced dopaminergic neurotransmission, in addition to its local anesthetic properties [52-55]. The underlying molecular neurobiology and genetics of cocaine addiction and its treatment with an emphasis reviewed elsewhere [56]. The investigation of single nucleotide polymorphisms (SNP) that encode amino acid substitutions in opioid receptors and ligands implicated in drug addiction, particularly those of the mu opioid receptor (MOP-r) gene system (*OPRM1*) that releases DA from neural synapse when activated, and those of the kappa receptor (KOP-r) that instead lower extracellular dopamine levels, have contributed understanding to the variability in drug addiction among susceptible individuals [57].

Clinicopathological Spectrum of Cocaine-Related Cerebral Vasculitis

Excluded Literature Patients

Since the first reported patient with possible association of cocaine and ischemic stroke [58], both stroke and cerebral vasculitis have been described in the literature as features of cocaine drug abuse. One clinical series of 28 patients [59] and another of 15 patients [60] failed to identify vasculitis by cerebral angiographic data, and in a pathologically studied patient at postmortem examination [59]. Moreover, vasculitis was not suggested in a review of 13 patients from nine published reports by the same authors [61] of cocaine-associated cerebrovascular complications. Other cases of presumed vasculitis suggested by intracranial arterial narrowing [62] in the absence of confirmed histopathology were contested as probably representing vasospasm following subarachnoid hemorrhage [63].

Pathologically-Verified Literature Patients

Only ten histologically verified patients, including six men and 4 women, age 21 to 39 (mean age 28 years) occurred in the absence of other possible known causes including concomitant infection by human immunodeficiency virus type 1 (HIV-1 or HIV) infection and known causative coinfections [25, 64-70]. In all but 1 patient [68] who had a long-standing cocaine habit with abuse sometime in the 6 months before admission, onset of neurological symptoms immediately followed cocaine use that was intranasal cocaine in 6 patients [66-70], intravenous in 2 [64, 65], smoked in 1 [64], and acquired via unknown modality in 1 [64]. Cerebral vasculitis was associated with cerebral hemorrhage in 3 patients [67, 68] and ischemia in the 7 patients [25, 64-66, 69, 70] that typically presented with abrupt onset of headache and focal hemiparesis so noted in 6 patients [67, 68, 25, 64], confusion or agitation [65, 66, 68-70], and grand mal seizures [66] that progressed to stupor, coma and death in 3 patients [25, 64, 66]. Lumbar CSF analysis showed lymphocytic pleocytosis of 10 to 65 cells/ cm³ with elevation of the protein content from 185 to 630 mg/dL [65, 70], and was completely normal in 2 other patients [64, 68]. Cerebral angiography performed in 7 patients showed an avascular mass in the patient with a putaminal hemorrhage [67], abnormal large named vessel occlusions or segmental narrowing in 3 patients [64, 68, 25], poor filling and irregularities in vessel appearance in 2 [69, 70], and normal in one patient [65].

The pathology of cerebral vasculitis was established by brain and meningeal biopsy in seven patients [64, 65, 67-70], at postmortem examination in two patients [25, 66], and by both in one patient [64]. The underlying pathology of cerebral vasculitis was non-necrotizing with transmural mononuclear cell inflammation affecting small arteries and veins in three patients [64, 66, 67] or veins alone in three patients [68-70], and perivascular cuffing of small arteries and veins in another [65]. In two patients, there was necrosis of small cerebral vessels associated with polymorphonuclear cell inflammation of small arteries and veins [68] or large named vessels [25]. Among three patients so studied at postmortem examination, non-necrotizing small vessel vasculitis was noted in the brains of two patients without evidence of systemic involvement [64, 66], while necrotizing large vessel vasculitis was found in both the brain and systemic organs [25].

Treatment consisting of corticosteroid was administered to seven patients, five of whom improved [64, 65, 68, 70] and two who died with refractory seizures despite anticonvulsant medication [64] or because of infection, coma and decerebration [25]. There was no mention

of treatment or outcome in 3 patients, [66, 67, 69] including two patients who succumbed to coma, hypoxic ischemic decerebration, and death [66, 67].

Etiopathogenic Mechanisms

Although cocaine-associated cerebral vasculitis has not been rigorously studied, several independent lines of experimental evidence suggest possible etiopathogenic mechanisms in susceptible individuals.

The first was the observed effects of cocaine in the induction of adhesion molecules and endothelial leukocyte migration across cerebral blood vessel endothelia walls particularly under inflammatory conditions, which may disturb the function of the blood brain barrier.

Cocaine increased the expression of the endothelial adhesion molecules intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and endothelial leukocyte adhesion molecule (ELAM)-1 on BMVEC with a peak effect on ICAM-1 expression between 6 and 18 hours after treatment in human brain microvascular endothelial cells (BMVEC) cultures and increased monocyte migration in an *in vitro* BBB model [71-74] constructed with BMVEC and astrocytes [75]. These effects of cocaine, exerted through a cascade of augmented expression of inflammatory cytokines and endothelia adhesion molecules, may contribute to the known cerebrovascular complications of cocaine abuse.

The second is the effect of cocaine on endothelial cell permeability and apoptosis as well as the induction of chemokines and cytokines. The immunomodulatory effects of cocaine on brain microvascular endothelial cells and its proinflammatory effects on induction of proinflammatory cytokines and chemokines was investigated using a human BBB model that included HIV neuroinvasion [76]. Cocaine increased the *in vitro* permeability of endothelial cells of the BBB model and induced apoptosis of mouse thymocytes in cultures of BMVEC and monocytes using an enzyme-linked immunosorbent assay (ELISA) of generated accompanied by up-regulation of macrophage inflammatory protein (MIP)-1, MIP-1 α , inducible protein (IP)-10, and interleukin (IL)-8 and TNF- α expression.

A third line of investigation has been the observed synergy of cocaine in facilitating pathogenic retroviral neuroinvasion, which may confer an independent risk factor for cerebral vasculitis. Both *in vitro* and *in vivo* studies have provided valuable tools in exploring the role of cocaine in mediating HIV-1-associated neuropathogenesis. The importance of drug abuse in conjunction with HIV-1 has been underscored by the ability of cocaine to induce retroviral replication in mononuclear cells [77] and enhance gp120-induced neurotoxicity [78].

OPIOIDS

Background

The opioid drugs comprise a large number of agonists, antagonists and mixed agonist-antagonists. Opioid overdose accounts for at least 16,000 deaths annually in the US [79] and occurs across sex, ethnic, age and geographic strata, and involves both medical and nonmedical opioid uses.

According to the Centers for Disease Control and Prevention (CDC), since 2003, opioid analgesic abuse [80] overdose deaths involving opioid analgesics exceeded those due to cocaine. For every unintentional overdose death related to an opioid analgesic, nine persons were admitted for substance abuse treatment, 161 reported drug abuse or dependency, and 461 reported nonmedical uses of opioid analgesic drugs [81].

Also known as diacetylmorphine, heroin was first synthesized by the Bayer Company in 1889 as a less addictive morphine sulfate substitute [82], however it has since become cheaper and more readily available.

There is extensive literature relating to the outcome of heroin abuse and overdose [83-87] with a reported the average mortality rate of 2% in regularly injecting persons, half of which is attributable to overdose and equal to 20 times the mortality rate expected in non-drug using peers.

Neuropharmacology

Opioids or narcotic drugs have pharmacologic properties similar to those of morphine that include the derivatives morphine, hydrocodone, oxycodone, hydromorphone, codeine, fentanyl, meperidine, methadone, and opium. Whereas the source of opioids is the exudate of seed from the poppy plant, heroin is derived from acetylation of morphine [21]. Heroin is administered intravenously, intranasal and subcutaneously.

A higher bioavailability of heroin is present after heating on foil for inhalation compared to smoking after heating. Intravenous injection leads to extreme euphoria that peaks at 10 minutes followed by profound sedation and analgesia that lasts for up to one hour. Opiate overdose produces the triad of coma, respiratory depression and meiosis. The medical complications of long-term heroin exposure includes endocarditis, pulmonary complications of embolism, pneumonia and granulomatosis or fibrosis, nephropathy, immunodepression, infection at the site of injection due to cellulitis, thrombophlebitis, and bacteremia, and hepatitis due to needle sharing [88].

It binds to endogenous opiate μ_1 receptors, which are responsible for most of the analgesic effects, and for the actions of the central nervous system and cardiovascular system leading to bradycardia, hypotension, and respiratory depression. Agonist actions at μ_2 receptors are responsible for respiratory depression, delayed gastrointestinal motility, meiosis, and physical dependence.

Agonist actions at kappa receptors lead to separate analgesia. Circulating serum morphine is transformed into morphine-3-glucuronide or morphine-6-glucuronide by the liver and the kidney. Most fatal and nonfatal overdoses occur when heroin is administered intravenously.

Clinicopathological Spectrum of Opioid-Related Cerebral Vasculitis

Excluded Literature Patients

Four often cited Brust, coworkers [58], Adle-Biasette, and colleagues [89] described patients with heroin abuse and cerebral vasculitis studied after death. In three patients [58] cerebral vasculitis was considered possible after exclusion of bacterial or fungal endocarditis,

focal ischemic during a period of shock after overdosage and hypoventilation, concomitant methamphetamine, drug allergy, and likely adulterants. One reported patient [58] died in methadone detoxification and postmortem revealed a massive hemorrhage of the right basal ganglia however, intracranial vessels were not examined. A second reported patient [58] developed unconscious followed by seizures, global aphasia and right hemiparesis in association with multiple occlusions on cerebral angiography before expiring, however neuropathological postmortem examination was not performed. A third reported heroin addict [58] who presented comatose with xanthochromic and bloody cerebrospinal fluid and died, was found to have a left intracerebral hemorrhage with normal large vessels on postmortem examination however, the smaller cerebral vessels were not commented upon.

Another often-cited pathological case [89] of possible cerebral infarction following inhalation of heroin in who was found dead one morning after the usual signs of recent heroin intake had ischemic cardiac lesions of varying ages and cortical watershed infarcts, reportedly had normal intracranial vessels at postmortem examination.

Confirmatory pathology was not sought among 5 often cited surviving heroin abusers [90-94] who presented with focal strokes on neuroimaging after inhalation [93, 94] or intravenous [90, 91] evidencing likely cerebral vasculitis on cerebral angiography; [90, 92], one of whom admitted to intermittent lysergic acid diethylamide (LSD) use [90]. All of the patients who had employed only heroin, cocaine or marihuana described by Halpern and Citron [38] in a report of necrotizing angiitis associated with drug abuse were included in the category of normal angiographic examinations, and their supporting pathology, even if available, was not described in the paper.

Pathologically-Verified Literature Patients

We could not identify any pathologically confirmed cases of heroin induced cerebral vasculitis reported in the literature, nor was cerebral vasculitis suggested as a likely occurrence in heroin abuse [95], heroin addiction [88, 96], or acute overdose [83]. Moreover, detailed neuropathological studies carried out on 134 victims of acute heroin intoxication including 18 who survived for periods of hours or days [97], who respectively demonstrated cerebral edema in conjunction with vascular congestion, capillary engorgement, and perivascular bleeding attributed to toxic primary respiratory failure; and ischemic nerve cell damage resembling systemic hypoxia, showed no evidence of cerebral vasculitis, and only one focus of lymphocytic perivascular inflammation. The brains of 10 intravenous drug abusers who died from heroin overdoses, including one due to gunshot injury [98] likewise showed no evidence of cerebral vasculitis at postmortem examination, manifesting only a few perivascular mononuclear cells associated with pigment deposition.

Etiopathogenic Mechanisms

The postulated mechanisms of opioid related neuronal and CNS vascular injury include increased oxidative stress, induction of inflammatory cytokines, and increased permeability of the BBB especially in intravenous drug abuse. Ramage and colleagues [99] described increased deposition of hyperphosphorylated tau in entorhinal cortex and subiculum of the hippocampus, AT8-positive neurofibrillary tangles in entorhinal cortex, and increase in β -

amyloid precursor protein (β APP) in both the hippocampus and brainstem of drug abusers compared to controls. Several postulated causative mechanisms included repeated head injury, hypoxic-ischemic injury associated with opioid induced respiratory depression, microglial associated cytokine release, and drug-associated neurotoxicity.

DRUG ABUSE AND HIV/AIDS

Background

Recognition of the propensity for cerebral vascular inflammation in association with HIV/acquired immune deficiency syndrome (AIDS) and drug abuse has provided new insights into the mechanisms of cerebral vasculitis.

Early in the HIV/AIDS epidemic, it was clear that a significant proportion of infected persons were intravenous drug users. Their associated risk behavior exposed them to infection through sharing of contaminated needles thereby increasing the risk of spread of HIV and other blood borne infections [100]. Among 50 patients with AIDS and neurological complication, six HIV-1 infected patients described by Snider and colleagues [101] were intravenous drug users (IVDU), the others being male homosexuals and recently arrived Haitian refugees. The two postulated periods in the neurobiology of HIV-1 when autoimmune disease manifestations can occur that appear to be significant for the development of cerebral vasculitis were shortly after seroconversion and before the spread of productive infection [98, 102]; and after initiation of highly active antiretroviral therapy (HAART) in association with the immune reconstitution syndrome (IRIS) [103]. The impact of IVDU in the development of cerebral vasculitis and other autoimmune sequel is not well understood. However there is an extensive literature suggesting an independent contribution of IVDU to immune suppression, breakdown of the BBB, microglial activation, and neuronal injury [104-110] and an additive or synergistic reinforcement of HIV-related brain damage by IVDU [111].

The timing of early HIV invasion has been difficult to ascertain based on the presence of one or more well-recognized clinicopathological HIV/AIDS syndromes including HIV encephalitis [112] HIV-associated dementia [113], and AIDS-dementia complex [114], all of which are indicative of symptomatic infection. HIV encephalitis is initially associated with myelin pallor and gliosis of the centrum semiovale found in more than 90% of brains from patients dying with AIDS [115]. With increasing severity of symptomatic disease, multiple glial nodules with the multinucleated cells characteristic of HIV encephalitis occur throughout the white matter, basal ganglia, cerebral and cerebellar cortex, brainstem and spinal cord. HIV has been demonstrated in monocytes and multinucleated giant cells by electron microscopy, immunocytochemical techniques and in situ hybridization. Guillemin [116] reviewed Vasculitides in the context of HIV infection.

Clinicopathological Spectrum of Drug Abuse and HIV/AIDS

HIV-Seropositive, Pre-AIDS Literature Patients

It has long been recognized that HIV antigens may be identified in CSF at, or shortly after seroconversion [117-119], and asymptomatic HIV-positive subjects [120] including seropositive men with normal CD4+ cell counts, neuropsychological, and neuroimaging, and normal neurophysiological investigations [121]. The examination of presymptomatic individuals has been virtually confined to intravenous drug abusers since other risk groups have a very low mortality before development of AIDS [106]. Gray and colleagues [122] described six patients with non-necrotizing cerebral vasculitis in a postmortem series of presymptomatic HIV-seropositive drug abusers, and Yankner and coworkers [123] with rapidly fatal necrotizing granulomatous angiitis of the brain without evidence of acquired immune deficiency, circulating HTLV-III or HIV-1 antibodies, described an analogous patient. Seven other patients were described by Bell and colleagues with lymphocytic infiltration of the walls of leptomeningeal and subarachnoid veins, without specific reference of cerebral vasculitis [102]. Gray and colleagues [122] studied two cohorts of 11 patients, one HIV-seropositive and non-AIDS, and the other HIV-seronegative heroin abusers, 10 patients of each died from heroin overdose and another of a fatal gunshot wound.

Neuropathological studies [122] showed varying degrees of vascular inflammation including "true vasculitis" exemplified by dense vascular inflammation extending through the vessel wall, associated with leptomeningitis in six of the 11 HIV-seropositive AIDS-negative patients. However, there was no mention as to whether inflammatory process involved arteries and vein or the vessel caliber. Vascular inflammation was comparatively mild or absent and restricted to a few perivascular mononucleated cells associated with pigment deposition, without transmural vascular inflammation or meningitis in the HIV-seronegative cohort. HIV immunocytochemistry was negative in both cohorts and multinucleated giant cells, considered the hallmark of productive HIV infection in the brain and an essential neuropathological feature of HIV encephalitis, were not seen. One year later, Bell and coworkers [102] described the neuropathological findings of 23 intravenous drug users from the Edinburgh HIV Autopsy Cohort who died suddenly after seroconversion but while still in the presymptomatic stage of HIV infection in comparison to 10 HIV-negative intravenous drug users, 12 non-intravenous drug user controls, and 9 patients with full-blown AIDS, who also died suddenly. Seven of the presymptomatic HIV-positive patients showed infiltration of T-cells in the walls of veins in association with low-grade lymphocytic meningitis; seven others demonstrated isolated lymphocytic meningitis, and one patient had focal perivascular lymphocytic cuffing and macrophage collections throughout the central white matter tissue of the brain and in basal ganglia. Neither conspicuous perivascular lymphocytic infiltration nor lymphocytic meningitis was noted in HIV-negative intravenous drug user controls or in those with no drug association, or others with full-blown AIDS.

Neuropathological examination in presymptomatic HIV-seropositive patients failed to reveal characteristic lesions of HIV encephalitis and none of the subjects showed immunocytochemical evidence of p24 antigen in brain tissue. Nearly a decade later, Bell and colleagues [105] reiterated that in more than 50% of pre-AIDS cases so studied, the brain was characterized by a low-grade lymphocytic meningoencephalitis in which T-cell infiltration was present in leptomeninges and the perivascular compartment, with an occasional HIV-p24

positive lymphocyte in the lymphocytic infiltrate, but not in brain parenchyma. According to the same authors [105] there was conversely no clear evidence of vasculitis among intravenous drug users with HIV encephalitis in the Edinburgh HIV autopsy cohort [124]. Yankner and colleagues [123] reported the clinicopathologic findings of a homosexual man with rapidly fatal cerebral granulomatous angiitis of the brain associated with isolation of human T-lymphotropic virus type III (HTLV-III) in CSF and brain tissue. Mononuclear cellular infiltrates were present at postmortem examination in the walls of affected large named arteries without involvement of small arteries and veins, and with rare microglial nodules and multinucleated giant cells.

The early CNS changes of HIV infection were investigated among hemophiliacs examined after sudden death from intracranial hemorrhage and liver cirrhosis [125] and in experimental animal models of simian immunodeficiency virus (SIV) syndrome [126] and feline immunodeficiency virus (FIV) infection [127]. They have comparable neuropathological changes of gliosis, occasional microglial nodules, perivascular mononuclear infiltrates, and occasional leptomeningeal meningitis in all three, characteristically without multinucleated giant cells or evidence of HIV in the brain [125-127]. HIV-infected cells were mainly perivascular and expressed macrophage markers in the SIV model [126] suggesting transit of virus across the BBB as the main source of entry into the CNS.

Moreover, the comparatively less pronounced vascular inflammation than that described in early HIV-infection associated with drug abuse, suggests that intravenous drug abuse contributes to vascular inflammation.

HIV/AIDS-Associated-IRIS Literature Patients

The introduction of HAART has changes the incidence, course and prognosis of the neurological complications of HIV infection concomitant with almost undetectable viral load in plasma and a rise in circulating T-lymphocytes [128]. One pathologically confirmed patient with cerebral vasculitis and van der Ven and colleagues [129] described IRIS. This HIV-seropositive homosexual man developed dysarthria and dysphagia after HAART with worsening and appearance of limb paresis after discontinuation of the medication. Treatment with corticosteroids preceded recommencement of HAART but there was worsening with discontinuation of corticosteroids. Biopsy of a hyperintense fronto-parietal lesion on T₂-weighted MRI showed small vessel lymphocytic vasculitis, with microglial activation in the surrounding parenchyma. A severe demyelinating leukoencephalopathy in association with intense perivascular infiltration by HIV-gp41 immunoreactive monocytes/macrophages and lymphocytes was described by Langford and colleagues [130] in seven postmortem patients. All were severely immunosuppressed and treated with HAART with presumed IRIS however, high not low levels of HIV replication were noted. However, there was no consideration of cerebral vasculitis. Confirmatory neuropathology was not sought however in a patient described by Patel and coworkers [131] with HIV-seropositive man who developed encephalitis 10 months after HAART in association with a lower thoracic dermatomal varicella zoster virus (VZV) rash.

Levamisole

Background

The anti-helminthic agent levamisole, first introduced for use in veterinary medicine was later discovered to have potent immunomodulation properties, prompting its application in inflammatory and oncologic conditions including rheumatoid arthritis, aphthous ulcers, and melanoma (132). The U.S. Food and Drug Administration as adjuvant therapy for the treatment of inflammatory conditions and cancer approved Levamisole. In Asia, it has been used as an anti-helminthic and pesticide agent.

Epidemiology

Levamisole was detected in cocaine bricks by the U.S. Drug Enforcement Agency in 2003 (133), noting an increase from 44.1% of specimens in 2008 to 73.2% in 2009 (134), signaling a rising public health problem. In 2011, Buchman and co-workers (135) reported a prevalence of 68% employing a combination of immunoassay and gas chromatography-mass spectroscopy detection methodologies. Other drugs noted in positive urine specimens included the opioid analgesics methadone (45%), codeine (16%), heroin/6-monoacetylmorphine (6%), and morphine or oxycodone (5%). The importance of detecting levamisole in urine concomitantly with cocaine in affected cases is in being able to ascertain its separate contribution to the observed neurotoxicity in suspected cases.

Neuropharmacology

Levamisole is 100- to 300-fold less potent than cocaine in blocking norepinephrine and dopamine uptake, and has a very low affinity for the serotonin transporter; and it does not trigger an appreciable substrate efflux. Nevertheless, the desired neuropharmacologic effects leads to its widespread contamination in cocaine production. It potentiates the euphoric effects of cocaine by inhibiting dopamine reuptake and forming amphetamine-like metabolites. Hofmaier and colleagues (136) studied the allosteric effects of levamisole and cocaine at 30 μ M, a concentration at which levamisole displayed already mild effects on norepinephrine transport but without an inhibitory action on cocaine. Levamisole metabolized to aminorex, an amphetamine-like substance that exerted strong effects on dopamine, serotonin and norepinephrine transporters in a manner that resembled amphetamine. They concluded that while the adulterant levamisole itself had only moderate effects on neurotransmission, its metabolite, aminorex, nonetheless exerted distinct psychostimulant effects and that after the cocaine effect “fades out,” the levamisole/aminorex effects “kicks in.”

Clinicopathologic Manifestations

Exposure to levamisole-adulterated cocaine is associated with a variety of well-described hematological, skin, renal and pulmonary pathologies (137) often in association with positive antineutrophil cytoplasmic antibody (ANCA) serology. Hematologic abnormalities include agranulocytosis and neutropenia, which occurs in a dose dependent fashion, which is not commonly associated with pure cocaine-linked side or a characteristic of drug-induced vasculitis. A distinguishing feature of levamisole-adulterated cocaine exposure is small vessel vasculitis (SVV) which involves the ear lobes and the skin overlying zygomatic arch or lower

extremities, often with purpuric plaques in a retiform pattern or central necrosis. Skin biopsy shows pathological involvement of superficial and deep dermal vessels associated with numerous neutrophils and eosinophils that surrounding and invade the walls of dermal vessels with extravasation of red blood cells, leukocytoclastic debris (nuclear dust), and fibrinoid necrosis on hematoxylin and eosin-stained tissue sections. Such findings are similar to children with chronic levamisole treated for nephrotic syndrome so noted in a minority of children who developed purpuric lesions of at least the ears and biopsies revealing cutaneous vasculitis (138). Although organ involvement has not been characteristic of levamisole-adulterated cocaine-induced autoimmune disease, there is an established association with proteinuria or hematuria, acute renal injury, focal necrotizing and crescentic pauciimmune glomerulonephritis in some cases, and increased titers to p-ANCA. As in other drug-induced vasculitides, pulmonary involvement can complete the triad of skin, kidney and lung pathology in the form of diffuse alveolar hemorrhages, idiopathic pulmonary hypertension, or other clinicopathologic presentations.

Multifocal Inflammatory Leukoencephalopathy

It has taken 25 years to recognize the causal association of levamisole-associated MIL in cocaine users. In 1992, Hook and colleagues (139) described three patients, ages 45 to 74 years, who developed a cerebral demyelinating disease within 3 to 5 months of beginning adjuvant therapy with 5-fluorouracil (5-FU) and levamisole. Two patients presented with progressive encephalopathy and ataxia, and a third had unexplained loss of consciousness. Brain MRI revealed multiple gadolinium-enhanced white matter lesions, predominantly in a periventricular distribution. Cerebrospinal fluid obtained in two patients showed oligoclonal bands (two patients) and pleocytosis (one patient). Pathological studies of brain biopsy specimens from two patients revealed cerebral demyelination and perivascular inflammation similar to multiple sclerosis (MS). There was clear improvement after discontinuation of chemotherapy and administration of corticosteroids. The pathogenesis was unclear, and the authors considered the etiological basis to be 5-FU toxicity although the role of levamisole was not excluded.

Three years later, Kimmel and colleagues (140) described a patient age 57 years, who developed progressive confusion and ataxia over a three-week period, five weeks after adjuvant therapy with levamisole for malignant melanoma. Brain MRI showed multifocal enhancing white matter lesions. Cerebrospinal fluid showed pleocytosis with an increased IgG index. The patient improved with a three-month tapering course of corticosteroids. The cause of the leukoencephalopathy in previously described cases (139) of 5-FU and levamisole was assigned at least in part, to levamisole.

One year later, Luppi and colleagues (141) described two patients, age 54 and 60 years, treated with adjuvant 5-FU and levamisole for colon cancer, who after 10 weeks and 6 weeks respectively from onset of treatment noted confusion, aphasia, ataxia, and progressive obtundation leading to decerebration (Case 1) and nasogastric feeding (Case 2). Brain MRI in both showed widespread bilaterally symmetric periventricular and hemispheric white matter hyperintensities compatible with MIL. Treatment with parenteral corticosteroids (Case 2) led to clinical improvement.

A decade later, Wu and coworkers (142) described a series of 31 patients with levamisole-induced MIL, including 7 from their institution and twenty-four from the medical

literature, treated with a combination of levamisole and 5-FU adjuvant therapy (21 patients) or levamisole alone (10 patients) for malignant cancer, most commonly colon cancer.

Onset of gait ataxia in two-thirds of cases, was delayed in those treated with combination 5-FU and levamisole compared with levamisole alone (11.7 weeks vs. 2.5 weeks). Brain MRI showed enhancing periventricular or supratentorial white matter lesions. Cerebrospinal fluid showed lymphocytic pleocytosis in 47% of cases. Treatment with corticosteroids and intravenous immunoglobulin (Ig) led to improved clinical status in 29 (94%) cases.

In 2009, Xu and coworkers (143) described the clinical and neuroradiological findings in 16 patients, age 8 to 52 years, treated with levamisole for recurrent aphthous ulcers or ascariasis infections noting weakness (75%), aphasia (50%), neurocognitive (50%), and facial palsy (44%) as the main presenting clinical features. Brain MRI showed typical plaque and round or oval demyelinating enhancing white matter lesions and hyperintense signal on T₂/FLAIR images. Brain biopsy in one case showed multifocal demyelinating lesions with lymphocytic perivascular cuffs. Treatment with corticosteroids and hyperbaric oxygen led was associated with full recovery.

In 2012, Blanc and colleagues (144) described a 29-year-old woman and active crack cocaine abuser with acquired immune deficiency syndrome (AIDS) presented with fever, malaise, and back pain and an unremarkable neurological examination. Cerebrospinal fluid showed acellular fluid with increased protein content and oligoclonal bands. A urine drug screen showed cocaine and opiates. Brain MRI showed lesions consistent with MIL. Sera later tested for both cocaine and levamisole by gas chromatography-mass spectroscopy were negative. The authors speculated that levamisole contamination was responsible for MIL citing that urine testing for levamisole would have been positive if performed at the time of cocaine detection.

In 2013, Yan and colleagues (145) described the clinical and neuroradiologic features of 15 patients, age 31 to 54 years, treated with levamisole for worm expulsion for two weeks to two months prior to onset of fever, headache, dizziness, neurocognitive disturbance, weakness, and visual impairment. Nine patients who underwent CSF examination showed only pleocytosis. Electroencephalography in all 15 showed high amplitude slow waves. Brain MRI showed multiple hyperintense T₂/FLAIR bilateral centrum semiovale and periventricular lesions (all patients), while two-thirds showed lesions in basal ganglia; with lesser frequency in the frontal (26%), occipital (6%), and temporal lobes (6%), brainstem or cerebellum (6%). Treatment with “hormone therapy” was effective in all patients.

In the same year, 2013, González-Duarte and Williams (146) described a 40-year-old woman with chronic daily use of cocaine admitted for acute confusion, aphasia, and fever. Cerebrospinal fluid showed neutrophilic pleocytosis. Brain MRI showed hyperintense signal in left parietal lobe white matter on T₂/FLAIR images. She developed sudden visual changes and hemiparesis 10 days later, and a week after, a new episode of expressive aphasia each associated with respective right and left frontal white matter lesions reminiscent of MIL. Complete recovery occurred in two weeks and she remained stable without further new episodes despite continued cocaine abuse. The authors speculated a relationship to levamisole adulteration.

In 2015, Vosoughi and Schmidt (147) described MIL in two cocaine abusers, age 25 and 41 years, who presented respectively with unilateral progressing to bilateral sensorimotor deficits; and confusion with impaired balance. Serial brain MRI in the first patient showed increasing bilateral T₂/FLAIR enhancing white matter hyperintensities in periventricular

white matter, pons and cerebellar peduncles, with similar presenting features in the second patients. Both patients improved with corticosteroids and plasma exchange. Urinary levamisole was not tested in either patient although the authors concluded that it was a likely cause of MIL in their cases.

Finally, Vitt and colleagues (148) described a case of MIL with positive urine testing for cocaine and levamisole in a cocaine abuser with a history of hepatitis C infection. This a 63-year-old woman presented with three days of progressive confusion, fever, and headache. Over two days she developed spastic quadriparesis and stupor. Cocaine tested positive in the urine. Brain MRI revealed T₂/FLAIR hyperintensities and incomplete ring-enhancement in periventricular subcortical white matter, many of which were ovoid shaped. Cerebrospinal fluid showed a lymphocytic pleocytosis and elevated protein content without oligoclonal bands. Gas chromatography-mass spectroscopy detected levamisole in the urine. High-dose intravenous methylprednisolone for five days followed by plasmapheresis was ineffective. The patient received intravenous cyclophosphamide with stabilization. Ten months later, the patient was minimally conscious with mutism and generalized spasticity.

Immunopathogenic Mechanism

The mechanisms underlying levamisole-adulterated cocaine-induced systemic pathology are not well understood but a causal relation to ANCA-associated disease is suggested by the correlation of disease pathology, clinical relapse with detectable autoantibodies, sensitivity to immune modulatory and immunosuppressive therapy, and predictable levamisole-induced histopathology. Levamisole potentiates the production of interferon- α and interleukin-2 as well as increases T-cell activation and proliferation, neutrophil mobility, adherence, and chemotaxis and increases the formation of antibodies to antigens (132). It acts as a hapten, triggering an immune response resulting in opsonization and leukocyte destruction. Levamisole may interact with neutrophil extracellular traps (NET) composed of a complex of deoxyribonucleic acid (DNA), histones, and neutrophil granules including myeloperoxidase (MPO), proteinase-3 (PR3), and human neutrophil elastase (HNE). Neutrophil extracellular traps release in response to stress and provide a source of antigen that can activate the immune system (137). Although there has not been a postmortem-studied case of MIL, for unclear reasons, such patients fail to demonstrate vasculitis in brain biopsy tissue or symptomatic vasculitic skin pathology, renal, hematologic, or pulmonary involvement in life

CONCLUSION

Drug abuse is a rare cause of histopathologically verified CNS vasculitis. Nonetheless, the complications of illicit substance use on the cerebral circulation can be highly lethal with secondary vasculopathy, hemorrhage and aneurysm formation especially when the illicit substances are delivered parenterally. With only a handful of confirmed patients in the literature, and rare association if ever, with progressive neurological deficits, there is generally little justification for invasive laboratory investigation, especially given the availability of highly accurate vascular neuroimaging techniques. Management rests upon avoidance of further exposure and minimizing the secondary neurotoxic effects of the abused substances and polypharmacy use.

ABSTRACT

Autoimmune encephalitis is a severe inflammatory disorder of the brain with diverse causes and a complex differential diagnosis including central nervous system vasculitis. Recent advances in the past decade has led to the identification of new syndromes and biological markers of limbic encephalitis, the commonest presentation of autoimmune encephalitis. Autoimmune encephalitis is associated with serum and intrathecal antibodies to intracellular and surface neuronal antigens against constituents of the limbic system neuropil. This has led to a reconsideration of a number of neuropsychiatric and neurocognitive disorders as having shared mechanisms of origin. The successful use of serum and intrathecal antibodies to diagnose affected patients, and their subsequent improvement with effective treatment has resulted in relatively few biopsy and postmortem examinations. In those available, there can be variable infiltrating inflammatory T-cells with cytotoxic granules in close apposition to neurons, analogous to microscopic vasculitis.

Keywords: autoimmune, encephalitis, hashimoto, encephalopathy

INTRODUCTION

According to Dalmau [1], for many years, the only known disorders associated with autoantibodies were myasthenia gravis and Lambert-Eaton myasthenic syndrome (LEMS).

These two predominantly B-cell peripheral nervous system (PNS) disorders targeted acetylcholine receptors or voltage-gated calcium channels resulting in reversible neuromuscular alterations that fully accounted for the observed symptoms and signs. In the central nervous system (CNS), paraneoplastic disorders associated with onconeural antibodies were cross-reactive with tumor nuclear and cytoplasmic neuronal antigens mediated by cytotoxic T-cells not B-cells. With the large group of undiagnosed encephalopathies, in particular syndromes characterized by limbic encephalitis, investigators returned to the laboratory to study the patterns of brain neuropil reactivity of newly recognized autoantibodies [2]. The result has been the recognition of newly characterized childhood and adult neurological and neuropsychiatric disorders termed autoimmune encephalitis or encephalopathy, mediated by antibodies against surface and intracellular antigens [3]. The successful use of serum and intrathecal antibodies to diagnose affected patients, and their subsequent improvement with effective treatment has resulted in relatively few biopsy and postmortem examinations. In those available however, the resulting neurodegeneration associated with autoantibodies appears to result from infiltrating inflammatory T-cells, especially those with cytotoxic granules in close apposition to neurons, analogous but distinct from microscopic vasculitis. With the ease of screening the serum and cerebrospinal fluid for a panel of pathogenic autoantibodies, and obtaining detailed morphologic and metabolic images of the brain specific for the disorders, autoimmune encephalitis is in the differential diagnosis of childhood and adult primary central nervous system angiitis [4, 5, 6], particularly before brain tissue biopsy is considered, or to avoid potentially harmful empiric immunosuppressant therapy [7]. This chapter reviews their historical background, epidemiology, clinical presentation, laboratory evaluation, histopathology, diagnosis and management of the autoimmune encephalitis

HISTORICAL PERSPECTIVE

In 1968, Corsellis and colleagues [8] coined the term limbic encephalitis (LE) noting a relation to bronchial cancer in three patients in the sixth to eighth decade of life. All three cases had subacute temporal lobe seizures, neuropsychiatric, and memory disturbances for two years before death. Postmortem examination revealed inflammatory lesions in limbic grey matter sections of the brain, notably in medial temporal lobe structures of the uncus and amygdala nuclei, and in the hippocampal, cingulum and dentate gyri. Case 2 had an undifferentiated non-metastatic lung carcinoma removed six months after onset of neurological symptoms, while two others had clinically unsuspected cancer at postmortem examination. Case 1 had a bronchial carcinoma restricted to a mediastinal lymph node without a primary lesion, while Case 3 had an unsuspected oat cell carcinoma infiltrating the main bronchi of both lungs and adjacent mediastinal nodes. Over the ensuing decades, attention turned away from limbic encephalitis and toward neurological autoimmune paraneoplastic syndromes with the discovery of several neuronal target antigens including Hu (ANNA-1) responsible for paraneoplastic encephalomyelitis (PEM) [9] in association with small cell lung cancer (SCLC); Ri (ANNA-2) responsible for paraneoplastic cerebellar degeneration [10] and motor neuronopathy [11] in association with breast cancer; and PCA-1 responsible for paraneoplastic cerebellar degeneration [12] in association with gynecologic

tumors. Other syndromes associated with paraneoplastic encephalitis were elucidated by Dalmau and colleagues [13, 14] in their descriptions of anti-MA1 and MA2 and testicular cancer; and the collapsin response mediator protein-5 (CRMP5/Cv2) in association with thymoma. Each with an intracellular target antigen, the resultant histopathology of these antibodies generally consisted of infiltrative cytotoxic (CD8+) T-cell destruction of neurons, with variable IgG and complement deposits in the CNS, with less helper (CD4+) T-cells, and generally absent B-cells. Bernal and colleagues [15] illustrated the role of infiltrating CD8+ T-cells in cell death by showing their close apposition to neurons.

In 2000, Bien and colleagues [16] revisited non-cancerous cases of LE in its relation to temporal lobe epilepsy. The interface of strictly paraneoplastic and autoimmune mechanisms was subsequently highlighted in the characterization of patients with stiff-person syndrome (SPS) associated with antibodies to glutamic acid decarboxylase (GAD); and the clinical neurological syndromes associated with voltage-gated potassium channel (VGKC)-complex antibodies. Solimena and colleagues [17] investigated the existence of non-paraneoplastic CNS autoimmunity in a patient with SPS, epilepsy and type-1 diabetes (T1D, and increased titers of oligoclonal CSF IgG. Both the serum and CSF produced identical intense staining of all gray-matter regions. GAD65 was thence an important autoantigen in T1D, being highly expressed in the cytoplasm of pancreatic β cells. GAD-derived peptides were presentable by main histocompatibility complex (MHC) class I molecules and recognized by CD8+ T-cells on the surface of β cells. Activation of CD8+ GAD-specific T-cells further differentiated into memory cells suggesting a pathogenic role in T1D. However, only patients with very high titers of GAD were associated with LE; and they typically presented with recent-onset temporal lobe epilepsy (TLE) and intrathecal secretion, defining a form of non-paraneoplastic LE. Other patients within the SPS spectrum harbored antibodies against other proteins of the GABAergic synapse, including amphiphysin and gephyrin, which were found to associate with lymphoma, and malignant tumors of the breast, colon, lung, and thymus [18].

Contemporaneously, the clinical phenotypes associated with autoantibodies to VGKC-complex ranged from peripheral nerve hyperexcitability (PNH), to Morvan's syndrome (MoS), and LE and autoimmune epilepsy [19, 20]. VGKC-complex antibodies were subsequently described in 2 patients with reversible LE [21]. Both patients were negative for typical paraneoplastic antibodies and with near-complete recovery, including one with recurrent thymoma after plasma exchange (PE), while the other patient recovered spontaneously without specific immunotherapy. The immunoprecipitation of VGKC-complexes linked a number of clinical syndromes that might otherwise have remained separate.

By 2010, Graus and colleagues [22] classified neuronal antibodies associated with syndromes resulting from CNS neuronal dysfunction into two groups according to the location of the target antigen. One group of well-characterized autoantibodies that recognized intracellular neuronal antigens included Ri, Yo, Hu, Ma2, CRMP5/Cv2 and GAD. These so called onconeural antibodies were useful in the designation of a specific paraneoplastic neurological disorder. Bien and colleagues [23] described qualitative and quantitative immunopathologic features of biopsy or postmortem brain tissue in 17 cases of autoimmune encephalitis (AE) associated with intracellular (IAg) (Hu, Ma2, GAD) or surface antigens (SAg) (VGKC-C and NMDA). Their studies noted higher CD8+/CD3+ ratio and more frequent appositions of granzyme-B (GrB)(+) cytotoxic T-cells to neurons, with associated

cell loss in the IAg-onconeural group compared to those in the SAg group. The exceptions were GAD cases that showed less intense inflammation and relatively low CD8/CD3 ratios compared to the IAg-onconeural cases. A role for T-cell-mediated neuronal cytotoxicity was found in encephalitides with antibodies against IAg, whereas a complement-mediated humoral immune mechanism was suggested in VDKC-complex encephalitis. There was apparent absence of both mechanisms in NMDA receptor encephalitis.

Bauer and Bien [24] suggested that neurodegeneration in brains of patients with antibodies against IAg was not simply induced by antibody reactivity with the target antigen, but rather by the inflammatory T-cells. To be pathogenic, they pointed out, the imputed antibody first had to transit the blood-brain barrier (BBB) and then the cell membrane of the target cell to a location where it could bind the pathogenic intracellular antigen. Depending upon protein conformation and folding, the antigenic site might be readily accessible before inactivation and ensuing irreparable cell damage. It is difficult to imagine that an intracellular antibody could easily overcome each of these obstacles. A major concern in managing these disorders has not only been prompt treatment of the tumor, but commencement of effective immunotherapy targeting mainly cytotoxic T-cells [25]. Vasculitis has not been a recognized mechanism of injury in intraneuronal antibodies, either in life or at postmortem examination [26].

The past decade witnessed the emergency of serum autoantibodies against SAg and synaptic-enriched regions leading to LE that spares the cytoplasm and nuclei of neurons such as those against GluN1 or GluN2/3 synaptic subunits of *N*-methyl-D-aspartate (NMDA) and glycine receptors; and to the amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl) propanoic acid (AMPA) receptor; and other novel neuropil antigens that localize to the cell surface of neurons and dendrites colocalized with synaptophysin and spinophilin [27, 28, 29, 30]. All supportive of LE or AE, these new antibodies share the property of strong immunolabeling of areas of dense dendritic network and synaptic-enriched regions in the neuropil of hippocampus. The clinical phenotype associated with the novel neuropil antibodies include dominant behavioral and psychiatric symptoms and seizures. With inconstant features of cognition and memory, brain-magnetic resonance imaging (MRI) and 2-deoxy-2-[fluorine-18] fluoro-D-glucose (^{18}F -FDG PET) abnormalities were less frequently restricted to the medial temporal lobe than in patients with classical paraneoplastic and VGKC-complex antibodies.

A role for the autoimmune dysfunction in neuropsychiatric illness has been sought since the 1930s when autoantibodies were first reported in a schizophrenia patient [31]. Since that time, there have been reports of specific autoimmune responses to self-antigens in psychosis, affective disorders, and other neurobehavioral abnormalities [32, 33]. Clinical neurologists, neuroscientists and psychiatrists, all have a stake in the emerging link between autoimmunity and resulting neurologic and psychiatric disorders in AE [34].

AUTOIMMUNE LIMBIC ENCEPHALITIDES

Three autoantibodies found in children and adults with LE target intracellular GAD65, and surface antigens of the NMDAR and VGKC-complex. Classically, the associated

symptoms, which evolve over days to weeks, include short-term memory loss, sleep disturbances, seizures, irritability, depression, hallucinations, and personality change.

Anti-GAD65 Encephalitis

Background

Autoimmunity targeting the 65 kilodalton (kDa) isoform of GAD65 encompass diverse autoimmune disorders such as T1D and rare neurologic disorders including LE, temporal lobe epilepsy (TLE), cerebellar ataxia, and large and small fiber peripheral and autonomic neuropathy [35].

Epidemiology

A review of adult-onset SPS showed a prevalence estimate of 1 in 1,250,000 [36] with a predominance of women, and average age of onset of 40 years. The frequency of high titers of anti-GAD antibodies defined an RIA value >1000 IU/ml in TLE of unknown origin is 21% [37] of cases, with the highest titers related to TLE. Affected patients are typically women with T1D, early-onset epilepsy, and concomitant hypothyroidism, psoriatic arthritis and Celiac disease, a third of whom reported onset of LE as the predominant feature, with supportive findings of amygdala and hippocampus signal intensities on brain MRI, and medial temporal hypometabolism on FDG brain PET. The levels of anti-GAD ranged from 1207 to 87 510 IU/ml, with absent OCB, and a ratio of serum/CSF GAD antibody levels >1 suggesting intrathecal synthesis. Malter [38] estimated the prevalence of GAD antibodies in LE to be 17%, noting a subgroup of patients with TLE who had very high titers equivalent to those with SPS, medial temporal inflammation on MRI, and concomitant LE. In the TLE cohort, GAD antibody encephalitis proved to be equally common to VGKC-complex antibodies but differed in younger age, female sex, and presentation of first seizure, CSF oligoclonal bands, and intrathecal autoantibody synthesis. Patients with high levels of GAD antibodies, and classic or other neurological syndromes not typically associated with GAD antibodies, were at higher risk for an underlying cancer.

Clinical Aspects

Gagnon and Savard [39] reviewed the clinical experience of 58 cases of GAD65-antibody LE beginning with the first reported case [40] inclusively through 2016, in 7 observational studies, 3 case series, and 21 published case reports providing a useful summary of the literature of anti-GAD65-associated LE. Among the 58 cases, there were 21 children and 37 adults, 59% of whom were female, with a median pediatric age of 10 years (range 1-17 years) and mean adult age of 39 years (range 19-70 years). Diabetes alone, generally T1D, was noted in 50% of cases, in association with thyroiditis, diabetes, Celiac disease, psoriasis, and common variable immune deficiency (CVID) respectively in 73%, 18%, 9%, and 9%. Cancer was noted in 6 (10%) cases, including 4 SCLC and 2 malignant thymomas, generally in men of mean age 61 years (range 38-70 years). The commonest presenting clinical features were seizures in 56 (97%) cases, most commonly refractory status epilepticus; cognitive impairment in 38 (59%) mainly affecting memory, language, executive function, and attention; psychiatric symptoms in 16 (28%) cases, most commonly depression, behavior,

perception, and anxiety. Less common clinical manifestations included fever, dysautonomia, cerebellar incoordination and headache respectively in 8 (12%), 7 (12%), 4 (7%), and 3 (5%) cases. The most common seizure presentation was refractory status epilepticus.

Cellular and Synaptic Antibody Effects

Low titers of anti-GAD65 antibodies, generally <20 nmol/L occur in T1D and in the general population, while cases of anti-GAD65-associated neurological disorders including LE are seen in the hundreds of nmol/L. Two GAD isoforms with distinct localizations and functions, GAD65 and GAD67, are expressed in presynaptic CNS GABAergic neurons, and in pancreatic β cells. Glutamic acid decarboxylase converts L-glutamate to GABA using pyridoxal-5'-phosphate (PLP) as a cofactor. GABA is the commonest inhibitory neurotransmitter in the CNS and the ligand for the inhibitory voltage-gated chloride channel GABA_A, and G-protein coupled GABA_B receptors. GAD67 commonly coexists with GAD65 antibodies in patients with neurologic autoimmunity. However GAD67 is rarely an autoantigen in isolation, found predominantly in the cytoplasm where it produces basal levels of GABA; whereas GAD65 is located predominantly in nerve terminals anchored to the cytoplasm-facing side of synaptic vesicles where it believed to synthesize GABA for neurotransmission supplementary to basal levels. The classification of high titers of anti-GAD65 autoantibodies has been problematic in being grouped with onconeural autoantibodies.

Laboratory Investigations

The dominant clinical phenotype of seizures, neurocognitive and neuropsychiatric disturbances in most patients with anti-GAD-autoantibody associated LE is explained by the frequent involvement of the medial temporal lobes; an inflammatory CSF with intrathecal secretion of the anti-GAD65 autoantibody, and oligoclonal bands. Bien and colleagues [41] described a 24-year-old woman with frequent temporal lobe seizures, non-paraneoplastic LE, and a serum anti-GAD65 antibody titer of 1:32,000, in whom T₂/FLAIR MRI evolved over a period of 8 months, demonstrating right hippocampal swelling and signal increase to sclerosis and atrophy on MRI commensurate with clinical progression. Among 58 literature patients [39], 45/58 (78%) patient MRIs were abnormal with specific involvement of the temporal lobes in 34 (59%), and multifocal abnormalities in 9 (16%); and 7 patient MRIs were normal. The results of electroencephalography (EEG) available in 35 cases, showed epileptiform discharges in 27 (77%), and focal temporal involvement in 19 (70%). Lumbar CSF so studied in 41 cases, showed pleocytosis in 11 (27%) with white blood cell (WBC) counts ranging from 7 to 114 cells/ul; and present oligoclonal bands (OCB) in one-half of cases. Hyponatremia was identified in 3 cases. There were significantly elevated titers of anti-GAD65 antibodies in both serum and CSF in 35 patients; and in either serum (in 18) or CSF alone in 3. Concurrent antibodies were reported in 11 cases, including those to GABA_A in 5 cases, and VGKC-complex or GABA_B in 3 cases. Antibodies to NMDAR, AMPAR, and onconeural antibodies were all absent. FDG brain PET imaging and MRI were complementary in 50% of cases [49]. Combining both MRI and PET, all patients had temporal lobe abnormalities. EEG may be useful in classifying the seizure type and directing the use of anticonvulsants especially when clinical seizures lack motor convulsions.

Histopathologic Correlation

The clinicopathologic features of anti-GAD antibody LE were described in a woman [41] who presented with frequent complex temporal lobe seizures at age 23. Over 8 months there was an evolution of right hippocampal swelling and signal increase on T₂/FLAIR MRI to sclerosis and atrophy. At the time of epilepsy brain surgery CSF showed 10 WBC and oligoclonal bands. Right-sided selective resection the sclerotic hippocampus showed strong encephalitic features. High-dose corticosteroid therapy administered over several months resulted in seizure-free status until weaning off 2.4 years later when she developed Cushing syndrome. She lapsed into a series of temporal lobe seizures and memory impairment accompanied by temporal left hippocampal swelling for which long-term corticosteroid and azathioprine therapy was started with slow clinical improvement. At follow-up 3.7 years later, she was still experiencing frequent partial temporal lobe seizures with memory deficits.

Bien and colleagues [23, 41] summarized the histopathologic features of selective resection of the sclerotic hippocampus in this patient that included neuronal loss and astrogliosis and a strong accumulation of inflammatory cells in the resected hippocampus. There was marked invasion of the hippocampus by lymphocytes that were mainly CD8+ T-cells with the cytotoxic effector molecule GrB, in addition to CD20+ B-cells and CD138+ plasma cells. The pattern of pyramidal cell loss was severe in sectors CA4 and CA3, with selective sparing of CA1 and 2. Surviving neurons were positive for MHC class I, fulfilling the prerequisite for attack by CD8+ T-cells. The authors [23] quantitated the number of parenchymal T-, B-, and plasma cells, macrophages and glial cells in 3 cases of anti-GAD65 autoantibody LE that included a previously reported case [41] differentiating them from the IAg-onconeural (Ma2 in 3 cases; Hu in 4 cases); SAg types in associated with VGKC-complex (4 cases) and NMDA receptor (3 cases); and Rasmussen encephalitis (22 cases) and neurodegeneration controls (25 cases). The percentage of CD8 T-cells in the IAg-GAD cases was intermediate (54%) between the IAg-onconeural and SAg cases. The CD8+/CD3+ ratio of the SAg cases was significantly different from the Rasmussen encephalitis controls. That ratio was lower than in the parenchyma confirming that CD8+ T-cells migrated into the parenchyma more readily than CD4+ T cells. Apposition of multiple GrB+ lymphocytes to single neurons, consistent with a specific cytotoxic T-cell attack in case GAD/3. Bien and colleagues [23] noted diffuse cytoplasmic IgG detected by anti-human IgG in both neurons and astrocytes in all cases similar to that of controls which they attributed to leakiness of damaged neuronal membranes. Staining of C9neo indicative of complement activation was negative in the IAg GAD cases. CD68+ cells comprised 0.2% in the IAg-GAD cases.

The finding of a reduced CD8+/CD3+ ratio of the IAg-GAD cases, all without concomitant tumor, was lower than the IAg-onconeural group. It was also within the highest ratios of the SAg group of NMDAR cases compatible with the hypothesis that T-cells were a necessary aspect for neuronal loss and hippocampal atrophy in the 2 GAD-associated LE (in GAD cases 2 and 3). Notwithstanding, the absence of an underlying malignancy could contribute to the long duration of disease and overall less intense inflammation. As noted by Bien and coworkers [23], the pathogenic role of GAD antibodies has not been certain because of the different associated clinical syndromes (SPS, cerebellar ataxia, TLE and LE). Multiple antibodies against IAg and SAg may explain the relatively low CD8+/CD3+ and GrB/CD3 ratios in the IAg-GAD cases.

Diagnosis and Treatment

The diagnosis of anti-GAD LE should be considered in patients with a clinical syndrome of temporal lobe seizures, and cognitive and psychiatric disturbances, brain MRI abnormalities on T₂FLAIR MRI implicating the medial temporal lobes; CSF pleocytosis and OCB; and EEG revealing temporal lobe epileptic or slow-wave activity, in association with high levels of anti-GAD65 autoantibodies on RIA. Most cases will fail to disclose an underlying malignancy. In the series of 58 literature case summarized by Gagnon and Savard [39] follow-up was available in 53 cases. Full recovery was noted in 4 (8%) cases, 3 of whom received corticosteroids alone, with intravenous immune globulin (IVIg), or in combination with PE; a fourth case received no immunosuppressant therapy and recovered. Death occurred in 4 (8%) cases, 3 of whom had an associated cancer. Sustained improvement was noted in 23 (43%) cases with followup of 96 months. A favorable outcome was noted in 45% of cases with positive CSF GAD65 antibodies compared to 56% of those with antibodies only in serum.

Anti-NMDA Receptor Encephalitis

Background

In 2007, Dalmau and colleagues [42] identified a new CNS antigen as NR1/NR2B12 heteromers of the NMDAR with predominantly neuropsychiatric symptoms from a cohort of 526 cases of noninfectious LE with antibodies against CNS proteins. The anti-NMDA receptor antibody appears to play a critical role in synaptic plasticity and memory. Although anti-NMDA receptor encephalitis is not by definition associated with cancer, 59% of patients had a tumor, most commonly benign-appearing cystic mature or immature teratomas tumors of the ovary. All showed serum or CSF antibodies to the NMDA receptor. A year later, the same investigators [27] described a case series of 100 patients with antibodies against NR1-NR2 heteromers of the NMDA receptor as measured by enzyme-linked immunosorbant assay (ELISA), 91 of whom were women, all with psychiatric symptoms or memory complaints. In addition, seizures were seen in 76 patients; 88 were unresponsive or had altered consciousness, 86 had dyskinesia, 69 had autonomic instability, and 66 showed hypoventilation. Three-quarters presented initially to a psychiatric service.

Epidemiology

Given its characteristic disease course, it is now assumed that a relevant proportion of patients previously diagnosed with encephalitis of unknown origin would have anti-NMDA receptor encephalitis [43] representing about 1% of all young patients' admissions to intensive care units (ICU). A French study [44] noted a frequency of anti-NMDA receptor encephalitis of 2% in febrile encephalitis that may be an underestimate because it excluded children. A multicenter, population-based, prospective study showed that anti-NMDA receptor encephalitis accounted for 4% of case of encephalitis in the United Kingdom (UK) making it the most common cause of AE after acute demyelinating encephalomyelitis (ADEM) in children [45].

Clinical Aspects

Clinically, anti-NMDA receptor encephalitis commences with nonspecific prodromal symptoms of headache, fever, nausea, or viral-infection like illness [46], but over days to weeks, seizures, neurocognitive and neurobehavioral complaints emerge including memory loss and frank neuropsychiatric manifestations of insomnia, mania, anxiety, depression, and paranoia [47, 48]. There can be movement disorders with oro-lingual-facial dyskinesia, autonomic manifestations, central hypoventilation, tachycardia and bradycardia. The eventual outcome of all patients was favorable in three-quarters who recovered or had mild deficits with immunotherapy, whereas one-quarter had severe persistent deficits or died. Relapses so noted in 25% to 30% of cases [49], were partly attributed to lack of treatment, while 12% of treated cases relapsed in the first two years in one long-term outcome cohort analysis [50].

Cellular and Synaptic Antibody Effects

Human embryonic kidney cells 293 (HEK293) ectopically expressing single or assembled NR1-NR2 subunits have been used to determine the epitope targeted by the anti-NMDA receptor, the extracellular N-terminal domain of the NR1 subunit. By quantitative analysis of the NMDA receptor in neuronal cell culture, there was a decrease in the numbers of cell-surface NMDA receptor, and NMDA receptor clusters in postsynaptic dendrites. Most patients with anti-NMDA receptor encephalitis have intrathecal synthesis of antibodies and numerous CD 138+ antibody-secreting plasma cells in perivascular, interstitial, and Virchow-Robin spaces with complement fixing IgG and IgG3 subtypes, as well as B- and T-cells in perivascular regions. Complement-mediated mechanisms in anti-NMDA receptor encephalitis studied in cultured rat hippocampal neurons tested for complement fixation [51] showed complement binding *in vitro* and in neural tissue of teratoma tumors, although not in the brains of affected patients.

Laboratory Investigations

Testing for NMDA receptor antibodies is recommended in patients who manifest encephalitic signs, psychiatric symptoms, seizures, and CSF inflammation, after exclusion of viral and bacterial causes of infection regardless of neuroradiologic investigation since the disorder may be associated with normal MRI findings in up to 50% of cases. The remaining one-half may include non-specific changes and abnormal T₂/FLAIR MRI hyperintensities in the mesial temporal lobe, cerebral or cerebellar cortex, basal ganglia or brainstem. There is typically no abnormal enhancement or hemorrhage. FDG brain PET may show hyper- or hypometabolism in the affected regions [52]. Up to 25% of patients have electrographic seizures. CSF analysis can show moderate lymphocytic pleocytosis, increased protein content, elevated IgG index, and CSF-specific oligoclonal bands which were typically negative at first testing, but can become positive later with disease progression in up to one-half of cases.

Histopathologic Correlation

The histopathologic aspects of NMDA receptor encephalitis have been studied in 14 cases, including 9 at postmortem examination, and 5 in brain biopsy tissue. Dalmau and colleagues [53] described 12 women with prominent psychiatric symptoms, amnesia, seizures, dyskinesia, autonomic dysfunction and altered consciousness. All had serum/CSF

antibodies that immunolabeled the neuropil of hippocampus/forebrain, in particular the cell surface of hippocampal neurons and reacted with NR2B, and to a lesser extent NR2A, subunits of the NMDA receptor. NR2B binds glutamate and forms heteromers (NR1/NR2B or NR1/NR2A/NR2B) that are preferentially expressed in the adult hippocampus/forebrain. Expression of functional heteromers, and not single subunits, was required for antibody binding. The CSF and serum of all 12 patients showed a distinctive pattern of reactivity with the neuropil of rat hippocampus, and the immunolabeling predominantly occurred with the cell membrane of neurons and was intense in the molecular layer of the hippocampus. Three patients age 14, 24 and 35 years of age (Cases 2, 6, 10) died, including one (Case 10) were previously reported [54], 3 to 6 months after symptom presentation. MRI showed T₂/FLAIR hyperintensities in the medial temporal lobes (Case 2); hyperintensity of the parietal sulci and enhancement of overlying meninges (Case 6); and a third (Case 10) showed normal findings. CSF in all three showed pleocytosis varying from 115 (Case 10) to 219 WBC (Case 6) with minimally increased or normal protein content, and positive oligoclonal bands. Immunofluorescence microscopy experiments demonstrated co-localization of antigens reacting with patient antisera and antibodies against NR2B, and co-localization of these antibodies in patients' tumor samples and in brain. Postmortem examination showed extensive gliosis, rare T-cell infiltrates, and neuronal degeneration predominantly involving, but not restricted to the hippocampus in all three. Microglial nodules and neuronophagia were rarely seen. In all cases, these findings predominated in the hippocampus but also affected other areas of the brain, brainstem, and spinal cord. There was intense IgG immunostaining of the hippocampi resembling rodent-staining of NMDA receptor in brain sections without complement immunostaining. The main epitope targeted by the antibodies is the extracellular N-terminal domain of the NR1 subunit. Patients' antibodies decreased the numbers of cell-surface NMDA receptor and clusters in postsynaptic dendrites, an effect that reversed by antibody removal. Tüzün and coworkers [55] extended the immunopathological analysis of Cases 6 and 10 reported previously by Dalmau and [53] noting that lymphocytic infiltrates were uncommon, and were rarely noted in the perivascular and leptomeningeal regions or scarcely distributed in the brain parenchyma. CD20+ B-cells and CD79a plasma cells were identified in the perivascular space including 1% cytotoxic T-cells and absence of GrB+, Fas and Fas ligand-positive cells. IgG, including deposits were noted in all areas of the CNS but most intense in the hippocampus, basal forebrain, and cervical spinal cord. Using HEK293 cells expressing NR1/NR2B, the NMDA receptor IgG were mainly IgG₁, but included IgG₂ and IgG₃ types. Tumor samples exhibited NR1/NR2-expressing tumor cells in varying amounts.

Camdessanché and coworkers [56] reported the postmortem findings of a brain biopsy specimen from an 18-year-old woman with NMDA receptor encephalitis who presented with subacute mood changes and facial jerks. Brain MRI showed foci of T₂ hyperintensities in the right frontal lobe, and CSF showed 21 WBC and oligoclonal bands. A frontal lobe showed that showed perivascular cuffing of CD20+ B-cells and a few CD138+ plasma cells, with few CD3+ T-cells or CD68+ macrophages scattered throughout grey and white matter and in perivascular spaces. Retrospective screening for anti-NMDA receptor antibodies was performed on a CSF sample that was positive at a dilution of 1:10, both in the neuropil of the rat hippocampus and in transfected HEK293 cells.

Martinez-Hernandez and coworkers [51] described 2 men, age 7 and 59 years, and three women age 5, 24 and 35 years, the latter two with ovarian teratomas, and anti-NMDA

receptor encephalitis who presented with subacute short-term memory deficits, psychiatric disturbances, seizures, movement disorders, and dysautonomia ranging from 22 days to 4 months. CSF showed protein elevation ranging from 94 to 219 mg/dL with oligoclonal bands; and brain MRI showed increased FLAIR signal in medial temporal lobes (Case 1), parietal cortex (Case 2), left temporal cortex (Case 3), and in the insula and anterior temporal lobes with atrophy in another (Case 5). Brain MRI was normal in Case 4. Treatment with combined immunotherapy in one patient who underwent a brain biopsy was effective, while the others died. One patient who died underwent earlier brain biopsy, and the remaining three patients were studied at postmortem examination. Patients' antibodies were able to fix complement on cultures of rat hippocampal neuron but were not detected in any of the brain regions of 3 patients, or in biopsies of 2 patients, all with anti-NMDAR encephalitis. The main histological findings were an abundance of infiltrating CD138+ plasma cells and plasmablasts in perivascular regions cuffing blood vessels, Virchow-Robin spaces, and lining the meningeal-brain surface in proximity to the CSF. Using cultures of rat hippocampal neurons, the patients' antibodies were able to fix complement but deposits of IgG were absent, nor was there complement immunostaining at postmortem examination or in brain tissue biopsies. In contrast to brain, tumor neural tissue showed complement immunoreactivity.

Bien and colleagues [23] examined brain biopsy tissue from 2 women and 1 man, age 17 to 22 years with NMDAR encephalitis, all three with encephalopathy lasting 2 months to 12 months, none with an associated tumor. Two were treated with immunotherapy before frontal (2 patients) or temporal lobe cortical biopsy. Serial MRI in one patient did not show hippocampal atrophy. Histopathology of the tissue specimens showed low density of T-cells, in the range of neurodegeneration controls. The ratio of perivascular CD8+/CD3+ was slightly elevated, and there were cytotoxic granules in some parenchymal T-cells, but no apposition of CD8++ T-cells to single neurons. Diffuse cytoplasmic IgG was evident in both neurons and astrocytes and C9neo deposition was present in the cytoplasm and on the surface of hippocampal CA4, dentate, and cortical neurons. The neocortex of NMDA receptor antibody-positive patients showed almost no inflammation, and no clear signs of neuronal loss. Even though NMDA receptor antibodies appeared to be involved in the clinical disease process, there was no evidence to suggest a classical mechanism of cytotoxic T-cell or humoral immune-mediated neuronal cell death. The possibility that a more active inflammatory infiltrate or antibody deposition could be found at an earlier disease stage in both the hippocampus and cortex, could not be excluded, although it was striking that MRI evidence of inflammation in the hippocampus was rare.

Collectively, the histopathologic findings were consistent with a selective and reversible decrease in NMDA receptor surface density and synaptic localization that correlated with patients' antibody titers. The mechanism of this decrease was selective antibody-mediated capping and internalization of surface NMDA receptors. This was supported by the experimental finding of Hughes and colleagues [57] who studied Fab fragments prepared from patients' antibodies that did not decrease surface receptor density. Subsequent cross-linking with anti-Fab antibodies recapitulated the decrease caused by intact patient NMDA receptor antibodies. These cellular mechanisms appear to be the cause of the specific titer-dependent and reversible loss of NMDA receptors. The loss of the subtype of glutamate receptors that eliminates NMDA receptor-mediated synaptic function may underlie the learning, memory and other behavioral deficits observed in affected patients.

Diagnosis and Treatment

Suggested criteria for the definite diagnosis of anti-NMDA receptor encephalitis [3] includes the presence of IgG anti-GluN1 antibodies in a suspected patient with subacute onset of psychiatric behavior or cognitive disturbances, seizures, movement disorder, and autonomic dysfunction; and abnormal EEG that shows focal or diffuse slowing or epileptic activity; and CSF pleocytosis or oligoclonal bands. Prompt diagnosis of anti-NMDA receptor encephalitis leads to improvement typically after removal and treatment of an offending cancer, or in the absence thereof. The demonstration of copious infiltrates of antibody-secreting cells in the CNS of affected patients provides an explanation for the intrathecal synthesis of antibodies, and implications for treatment used to arrest and reverse the disorder employing intravenous immunoglobulin (IVIg), corticosteroids, cyclophosphamide, or rituximab.

Given its characteristic disease course, it is now assumed that a relevant proportion of patients previously diagnosed with encephalitis of unknown origin would have anti-NMDA receptor encephalitis [43] representing about 1% of all young patients' admissions to ICU. A French study [44] noted a frequency of anti-NMDA receptor encephalitis in 2% in febrile encephalitis that could be an underestimate because of the exclusion of children. A multicenter population-based prospective study showed that anti-NMDA receptor encephalitis accounted for 4% of case of encephalitis in the UK, making it the most common cause of AE after ADEM in children [45].

Anti-VGKC-Complex Encephalitis

Background

About the same time that MoS was described, anti-VGKC-complex antibodies were determined using RIA in patients with noninfectious AE [19]. While the disorder was generally termed LE, the term limbic encephalopathy was also used as more patients were found to be seropositive without evidence of classical features of hyperintense signal intensities in the medial temporal lobes on brain MRI, and CSF inflammation [19].

Alteration of trans-synaptic scaffolding systems in AE that affects neuronal cell adhesion molecules are crucial for proper synapse formation and adhesion, plasticity, and function. In both developing and mature neurons, these molecules serve to recruit and anchor pre- and postsynaptic proteins to appropriate synaptic localizations, allowing for normal synaptic transmission. Autoantibodies against the VGKC-complex detected by RIA in the sera of patients with AE do not bind directly to VGKC-complex channel proteins proper, but instead to synaptic and axonal neuronal proteins that co-precipitate with detergent-solubilized VGKC [58, 59].

Attention has focused on identifying the principal autoantigens in the VGKC-complex and expanding the spectrum of corresponding phenotypes. Initial reports [60, 61] suggested that patients' antibodies were bound to the VGKCs Kv1.1 and Kv1.2. Subsequent studies showed that leucine-rich glioma-inactivated protein 1 (LGI1) LGI1, and contactin-associated protein-like2 (CASPR2) were the main autoantigens [58, 59] which associated with transiently expressed axonal glycoprotein (TAG1), post synaptic density protein-Drosophila disc large tumor suppressor-zonula occludens-1 protein (PDZ), and the ankyrin-spectrin

protein in both the peripheral and CNS. Antibodies against contactin-2 usually occur in association with those targeting LGI1 or Caspr2 were identified in other disorders, raising doubts about their importance. There is a diversity and overlap of neurological phenotypes associated with VGKC-complex-IgG in the serum and CSF, and distinct Ig-subtype specificity. The commonest presentation of VGKC-complex autoantibodies is LE in the CNS, and neuromyotonia or MoS in the periphery.

Epidemiology

In the UK, where the incidence of encephalitis is estimated at 5.23 cases/100,000/year based upon admissions to the National Health Service between 2005 and 2009, Granerod and colleagues [62] estimated the incidence of encephalitis as 4.32 cases/100,000 population/year. A capture–recapture model estimated the incidence of encephalitis to be 8.66 cases/100,000/year. Two percent of patients ($n = 216$) had >1 encephalitis admission during the study period; and the incidence did not change (4.20 cases/100,000/year) when subsequent admissions of these patients were excluded from the analysis. By using data restricted to the primary diagnostic field, the overall mean incidence was 2.75 cases/100,000/year (95% CI 2.39 cases–3.10/100,000/year). The results of multivariable analyses showed that compared with 2005–2006, incidence in all subsequent years was slightly higher but with little evidence of a trend ($p = 0.19$). The incidence rate was highest among patients <1 year of age, and in those >65 years of age. A retrospective study that reviewed antibodies to VGKC, LGI1 and CASPR2 in 46 children with severe acute encephalitis identified only one affected child (2.2%) among 46 children [63].

Clinical Aspects

Among 64 patients with VGKC-complex encephalitis [64] the clinical features overall included neuropsychiatric features, disorientation, confusion, or amnesia in 100% of patients; tonic-clonic seizures in 92%, delusions in 21%, hallucinations in 17%, agitation in 6%, pain in 4.7%, and peripheral neuropathy in 1.6% of cases. Neurocognitive complaints, psychiatric symptoms and seizures typical evolve over days to weeks, occasionally acutely, but more often insidiously over months before coming to medical attention. The finding of an apparent dementia in 72 affected patients was studied by Flanagan and colleagues [65]. Responsiveness to immunosuppressant and immunomodulatory therapy was predicted by seropositivity for neuronal VGKC-complex antibody more than calcium channel or neuronal acetylcholine receptor ($P = .01$). Up to 40% of patients may also manifest frontal lobe and frank psychiatric features. Parthasarathi and colleagues [66] described a 58-year-old man with panic attacks and psychogenic non-epileptic seizures who later developed delusions and hallucinations followed by confusion. He was found to have VGKC-complex antibodies and treated with immuno-modulatory therapy leading to near complete recovery. Bettcher and coworkers [67] delineated cognitive strengths and weaknesses among 12 subjects with VGKC-complex encephalitis noting mild to moderate impairment in memory and executive functions, with variable impairments in language and sparing of visuospatial skills that correlated with MRI findings of T_2 /FLAIR hyperintensities in medial temporal lobe (10/10) and basal ganglia (2/10). Serial cognitive examination revealed heterogeneity in cognitive function.

Seizures occur in up to 90% of cases and are most commonly focal in nature, with infrequent generalization, manifesting typical medial temporal lobe signature with hand and

orofacial automatisms. Three seizure semiologies, ictal bradycardia, piloerection, and fasciobrachial dystonic seizures (FBDS), show a strong associations to LE associated with LGI1 antibodies. FBDS consist of brief frequent episodes abnormal unilateral and bilateral movements of the arms, sometimes the ipsilateral muscles of the face, and more rarely the leg. Video electroencephalography shows an epileptic origin of these myoclonic-like movements however regular EEG with scalp electrodes often misses an interictal focus. If FBDS are recognized early, and serum LGI1 antibodies are detected, immunotherapy prevents progression to frank LE, which in one study arose after a median delay of 36 days. Kalachikov and colleagues [68] described autosomal dominant lateral temporal epilepsy (ADLTE) characterized by partial seizures and preceding auditory signs in the *LGI1/epitempin* gene expressed on chromosome 10q24. Mutations in this gene introduce premature stop codons and prevents production of full-length protein from the affected allele. Although LGI1 haploinsufficiency causes ADLT, the underlying molecular mechanism that results in abnormal brain excitability has instead been attributed to dysregulation of synaptic AMPA receptors in hippocampal neurons in the epileptic LGI1 knock-out mouse [69]. Fukata and colleagues [70] proposed that extracellularly secreted LGI1 linking two epilepsy-related brain receptors, a disintegrin and metalloproteinase domain 22 (ADAM22) and ADAM23, organize a transsynaptic protein complex that includes presynaptic potassium channels and postsynaptic AMPA receptor scaffolds. The lack of LGI1 disrupts this synaptic protein connection and selectively reduces AMPA receptor-mediated synaptic transmission in the hippocampus.

Younger [71] described new-onset FBDS and memory disturbances in association with distal large and painful small fiber peripheral neuropathy, dysautonomia without systemic malignancy in a patient with extrathecal VGKC-complex antibody production. Epidermal nerve fiber studies confirmed small fiber neuropathy in association with abnormal autonomic laboratory testing.

Neuropathic pain as a manifestation of VGKC-complex autoimmunity was noted in 316 (4%) of 1,992 patients evaluated neurologically at a tertiary referral center [72] that was typically subacute in onset, nociceptive, regional, or diffuse. In those suspected of peripheral neuropathy with mild subjective loss of temperature and pain attributed to small fiber dysfunction, electrodiagnostic studies show variable minor reduction of sural sensory nerve action potential amplitudes with motor hyperexcitability. The VGKC-complex antibody titers were often low (0.02-0.1 nM) and antibodies to GLI1 or CASPR2 were present in 28% overall, with the latter most common (7%).

Autonomic involvement was noted in 29% of the cohort studied by Klein and colleagues [72], and in 3 (60%) of the patients described by Lahoria and coworkers [73]. Hypothermia was described in association with VGKC-complex antibody-associated LE in 4 patients [22], Patient 1 of whom had concomitant neuropathic patient, and in the absence thereof in the others who were conjectured to have otherwise disturbed hypothalamic thermoregulatory mechanisms as the cause for dysautonomia.

Cellular and Synaptic Antibody Effects

LGI1 is a secreted synaptic protein that associates with, and regulates Kv1.1 and Kv1.2, as well as AMPA (128). Caspr2 is a transmembrane axonal protein of the neurexin IV superfamily that localizes to the juxtaparanode of myelinated axons, and its extracellular domain interacts with contactin-2, where it connects with the cytoskeleton via protein 4.1B.

Caspr2, contactin-2 and protein 4.1B, all of which are necessary to concentrate Kv1.1 and Kv1.2 channels in the juxtaparanode. Lai and colleagues [58] studied proteins associated with Kv1.1 and Kv1.2, noting that VGKCs themselves were the autoantibody targets, explaining the diversity of symptoms among patients with these antibodies. LGI1 is primarily a CNS protein, and LGI1 antibodies are associated with LE, seizures, and hyponatremia. LGI1 antibodies cause reversible CNS synaptic dysfunction by several mechanisms. The antibodies may prevent binding of LGI1 to the receptors that it regulates, or they might act on the LGI1–ADAM protein complex. Alternatively, LGI1 antibodies could disrupt currents mediated by Kv1.1 and Kv1.2, and/or impair AMPAR function, either indirectly by blocking LGI1-mediated regulation of these proteins or directly by disrupting the entire protein complex. The identification of LGI1 as a major target of so-called VGKC antibodies clarifies several aspects of the associated disorder.

Caspr2 antibodies are associated with autoimmune encephalitis, peripheral nerve hyperexcitability, and MoS. Peripheral nervous system manifestations may precede or follow those of the CNS by up to several years. Some affected patients may have an associated thymic tumor, but most do not. Mutations in the human gene encoding Caspr2 (*CNTNAP2*) are associated with autism, epilepsy, Tourette syndrome, cortical dysplasia, obsessive–compulsive disorder, Pitt–Hopkins syndrome, and other mental disabilities. Mice with a *caspr2* deletion show analogous behavioral defects and symptoms [74]. Interestingly, common variants of the *CNTNAP2* gene in healthy individuals are associated with abnormal language processing and are a risk factor for autism [75]. Caspr2 antibodies act by disrupting axonal potassium currents. Factors such as differences in time to establishment of intrathecal antibody synthesis, or in the structure of tight, septate-like junctions of myelinating cells around the axons may explain this variability. The VGKC–complex antibody levels also broadly differ between the different syndromes, with highest levels in LE and FBDS, moderate levels in MoS, and lowest levels (often <400 pM) in PNH.

Laboratory Investigation

The high proportion of VGKC-complex IgG-seropositive patients whose serum samples lack LGI1 IgG and CASPR2 IgG specificities, suggests that other VGKC-complex molecular targets remain to be discovered. Only about 4% to 5.5% of unselected cases were seropositive by RIA with confirmatory retesting using 125I- α -dendrotoxin alone (radioligand for Kv1.1, Kv1.2, and Kv1.6 channels) [76, 77], making the test unreliable as a screen for LE without further subtyping for LGI1 and CASPR2-IgG. So selected, 26% to 28% of seropositive VGKC sera revealed reactivity with LGI1 and/or CASPR2-IgG, with a significant association between LGI1-IgG-positivity and cognitive impairment and seizures ($P < .05$), and CASPR2-IgG-positivity and peripheral motor excitability ($P = .004$), however neither autoantibody was pathognomonic for a specific neurologic presentation. There has been concern for screening of unselected sera for VGKC-complex antibodies by RIA. It can be argued that VGKC-complex RIA antibody test should be used as initial screening to select positive samples that could then be confirmed by LGI1 or CASPR2-IgG antibody subtyping, however the latter may also be positive in selected VGKC-complex antibody-negative sera by RIA. Paterson and colleagues [78] noted positive VGKC-complex antibody values (>400 pm; >0.4 nM) that were likely to be relevant in LE and related syndromes, as well as low-positive values (<400 pm; 0.1–0.4 nM) in 32/44 cases considered to be non-autoimmune, 4 (13%) cases of which were found to have a definite or probable paraneoplastic neurologic disorder, neuromyotonia

or MoS. Ances and colleagues [30] noted that the RIA used in the clinical analysis of VGKC-complex antibodies identified a limited number of subunits (Kv1.1, Kv1.2 and Kv1.6) but that it was reasonable to speculate that antibodies to other subunits, K (+) channel families and VGKC ion channels might also associate with LE.

Cerebral imaging studies in VGKC-complex antibody associated LE show highly variable results. Both mesial temporal lobe hypometabolism on FDG brain PET, and hypermetabolism have been described [79, 80, 81]. In a patient with VGKC-complex LE [80] who did not definitively demonstrate structure abnormalities on serial brain MRI over time despite ongoing temporal lobe seizures captured on video-EEG, FDG brain PET fused with gadolinium-enhanced MRI later showed bitemporal hypometabolism. Baumgartner and colleagues [81] identified 9/18 (50%) patients positive for non-paraneoplastic antibodies against neuronal surface antigens (VGKC or NMDA-R), 2 of whom displayed mesiotemporal hypermetabolism on FDG brain PET, with 4 others were rated normal, and 3 displayed hypermetabolism outside the mesiotemporal region. The fraction of abnormal scans employing MRI was lower (10/16; 62.3%) than FDG brain PET (14/18; 77.7%).

CSF results were equally variable in VGKC-complex autoimmunity. Jarius and colleagues [82] performed 29 lumbar punctures in 17 patients with VGKC-complex LE noting normal findings in up to 53% of CSF specimens. There were no significant differences between the CSF findings and the titers of serum VGKC-complex autoantibodies. Slight pleocytosis, mainly consisting of lymphocytes and monocytes, and elevated total protein concentrations were present in 41% and 47%, respectively. A disturbance of the integrity of BBB was found in 6 (35%) patients based upon an abnormal CSF/serum humoral immune response. Absence of CSF-specific OCB, considered a marker of autochthonous antibody synthesis within the CNS in all patients [82] suggested an extrathecal origin of VGKC-complex autoantibodies. Vincent and colleagues [19] reported the CSF findings in 10 patients, all with VGKC-complex antibody-associated LE, noting mild lymphocytosis and mild or moderately raised protein content in one-half. OCB were noted in 1 patient, while 6 other OCB were identical to serum. VGKC-complex antibody assays on matched serum and CSF showed antibodies levels of the latter present in 4 patients that varied between <1 and 10% of the serum, and beneath 10% in one patient with the lowest serum value. These findings were consistent with extrathecal synthesis of VGKC-complex antibodies.

Irani and Vincent [64] estimated features of peripheral neuropathy in 1.6% of VGKC-complex antibody-positive LE cases. Lahoria and coworkers [73] described 5 patients with painful polyneuropathy, all positive for VGKC-complex autoantibodies (range 0.08 to 1.18 nM), two of whom had antigens positive for CASPR2 and LGI1-IgG, both at low VGKC-complex antibody titers (respectively 0.08 and 0.16 nM/L). Electrodiagnostic studies showed length-dependent sensorimotor polyneuropathy that was concordant with abnormal indices of axonal degeneration or demyelination in 4 nerves, and the latter with quantitative analysis of semithin sections in 2. All 5 showed absence of inflammatory cell infiltration. By comparison, the symptoms of small fiber neuropathy, which arise from dysfunction in nociception, temperature and autonomic modalities are most adequately assessed by epidermal nerve fiber density in a 3 mm punch biopsy of skin from the later calf and thigh, and a combination of cardiovascular, sudomotor and adrenergic functions tests with comparison to controls.

Histopathologic Correlation

Eight patients with VGKC-complex LE were studied histopathologically, including stereotactic brain biopsy in 3 [19, 23] at epilepsy surgery in 1 case [23], and at postmortem examination in 4 patients [23, 83, 84, 85]. Vincent and colleagues [19] described a 56-year-old man with 7 month history of confusion and memory impairment who developed partial focal seizures, anxiety and delusions. CSF showed mild pleocytosis and brain MRI showed unilateral left medial temporal lobe signal change with focal slow activity on EEG. The serum VGKC antibody titer was 2224 pM (normal 0-100pM; >400 pM highly elevated). Histopathology of a stereotactic biopsy of the left amygdala showed positive staining for perivascular and parenchymal CD45+ lymphocyte infiltrates, astrogliosis, and CD68+ microglial activation. He was received a course of intravenous dexamethasone with a slight beneficial response with persistent memory deficits. Follow-up brain MRI showed evolution of bilateral hippocampus atrophy and signal changes.

Dunstan and colleagues [83] reported a 78-year-old man with a 2 week history of confusion, cognitive impairment and hyponatremia. Brain MRI showed increased signal in the right medial temporal lobe with subcortical white matter changes. Cerebrospinal fluid was normal. Assay for VGKC antibodies were 1637 pM by RIA. He received anticonvulsants but deteriorated due to sepsis and died. Postmortem examination showed no evidence of a malignancy. The brain showed severe neuronal loss with multiple reactive astrocytes, macrophages, and scattered T-cells in the right amygdala nucleus and adjacent hippocampus.

Park and coworkers [84] described a 65-year-old woman with a 3 month history of amnesia, disorientation, memory loss, and partial complex seizures. Brain MRI was normal and CSF showed 17 WBC. EEG showed mild diffuse slowing. She later developed hyponatremia and serum VGKC-complex antibodies were 1.73 nmol/L (normal < 0.02 nmol/L) by RIA. Whole body FDG-PET showed mediastinal adenopathy. She was treated with intravenous corticosteroids for 5 weeks without improvement and later died. General autopsy limited to the chest showed no malignancy. Postmortem examination of the brain showed mild focal perivascular T-cell lymphocyte cuffing and infiltrates of overlying meninges and parenchyma of the cingulate gyrus, hippocampus, and amygdala and midbrain.

Khan and coworkers [85] reported a 56-year old man with a 4 month history of confusion, disorientation and seizures. A serum VGKC antibody titer was 3,327 pM by RIA and there was hyponatremia. Brain MRI showed left hippocampal atrophy on T₂/FLAIR images. General postmortem examination showed no malignancy. Examination of the brain showed pathological changes in both hippocampi and right amygdala regions comprised of pyramidal neuronal cell loss in the CA4 region, marked activation of CD68+ microglia and reactive GFAP+ astrocytosis extending to the subiculum, less so near the joining of the parahippocampus gyrus. There were perivascular infiltrates of CD20+ B-cells and a few CD4+ T-cells especially in the right hippocampus.

Bien and colleagues [23] summarized the histopathologic findings in the brain of 4 cases, 3 men and 1 woman, age 33 to 68 years, with LE (3 patients) and multifocal encephalitis in another, ranging from 5 to 9 months. Serum VGKC antibody titers were 167, 288, 958 and 2224 Pm respectively. Serial MRI showed an evolution from hippocampal swelling with T₂/FLAIR signal increase to frank hippocampal atrophy and increased signal intensities. Histopathologic examination including quantitative immunocytochemical studies showed variably intense inflammation and overall lower CD8/CD3 ratios, although there were GrB)+ T-cells present in the lesions without opposition to neurons or release of FrB, therefore T-cell

cytotoxicity was not a major contributor. Immunoglobulin and complement deposition on neurons was a prominent finding, and terminal deoxynucleotidyl transferase dUTP nick and labelling (TUNEL) reaction in the same area demonstrated acute neuron cell death suggesting antibody and complement mediated neuronal cell damage in these patients. The authors [23] noted that IgG4 rather than IgG1 antibodies dominated in the sera of those with VGKC-complex LE.

Diagnosis and Treatment

Suspected patients with new-onset and rapid progression of memory deficits, seizures, or psychiatric symptoms suggesting involvement of the limbic system; bilateral medial temporal lobe abnormalities on T2/FLAIR MRI, and CSF pleocytosis combined with TLE or slow-wave activity on EEG should be screened for VGKC-complex antibodies, with detection of LGI1 and CSFPR2 by RIA. The diagnosis of VGKC-complex LE can be established in suspected cases when serological studies are combined with clinical, neuroradiologic and CSF inflammatory parameters, and a reasonable exclusion of alternative diagnoses. If so, immunomodulatory and immunosuppressive therapy should begin. Less than one-half of affected patients fail to improve with first-line therapy employing IVIg, PE, or corticosteroids, needing to advance to second-line agents including cyclophosphamide and rituximab.

Bataller and colleagues [86] noted that treatment-responsiveness of LE was especially favorable among patients with antibodies to the VGKC-complex with overall improvement in two-thirds or more of patients. However, a favorable response to therapy was not limited to patients with VGKC-complex antibodies but extended to novel-cell-membrane antigens (nCMAg) expressed in the hippocampus. If the autoantigens were unknown but found to be highly enriched in neuronal cells membranes of the hippocampus, these antibodies were likewise associated with a favorable outcome emphasizing the usefulness of immunohistochemistry with PFA-fixed tissue and cultures of live hippocampus rat neurons in the analysis of highly-suspected patients with LE. The salutary effect of immunotherapy in the management of seizures in VGKC-complex antibody-associated LE is well supported by the autoimmune basis of FBDS [87].

HASHIMOTO ENCEPHALOPATHY

For nearly half a decade, investigators have been pursuing an associated rare encephalopathy associated with Hashimoto thyroiditis (HT). In 1966, the British neurologist, Lord Brain and colleagues [88] first described the entity of Hashimoto encephalopathy (HE) in a 40-year-old man with 12 ictal and stroke-like episodes of confusion and agitation one year after onset of treated hypothyroidism. The cerebral disorder remitted completely after 19 months commensurate with a decline in high serum thyroid- antibody levels. Treatment with prednisone and an anticoagulant for 3 months was ineffective. His neurologic symptoms remitted while he was taking only levothyroxine. The authors concluded that the likeliest explanation for this protracted and stuttering brain disorder was localized cerebral edema due to antibody-mediated autoimmunity, and that antibody studies in future cases of unexplained encephalopathy would show whether their findings constituted a syndrome or coincidence.

Jellinek and Ball [89] extended the results of Brain and colleagues [88], describing the original patient, who at age 62, later died 12 years later of an unrelated cause. Postmortem examination showed virtually no remaining thyroid tissue and atheromatous cerebrovascular changes with splenic atrophy. The authors postulated that underlying autoimmunity was the cause Hashimoto's thyroiditis and encephalopathy, and splenic atrophy. Almost one half decade later, Rowland and colleagues [90] characterized the clinicopathologic aspects of HE beginning with the patient described by Lord Brain and coworkers [88] and ending in 2002, adding a case of their own. The diagnosis of Hashimoto's encephalopathy, as described by Rowland and coworkers [90], which rests on the presence of HT with measurably high titers of TPO or Tg antibodies, clinical encephalopathy, and absence of cerebrospinal fluid evidence of bacterial or viral infection, serves as the standard for case selection. However then as now, it is unknown whether anti-thyroid antibodies and concomitant thyroid dysfunction contribute to the pathogenesis of HE.

Clinical Presentation

In the series of Rowland and coworkers [90] the mean age at onset of symptoms of Hashimoto's encephalopathy was 44 years (range, 9-78 years); 19 of whom were boys or girls, age 18 years or younger. Among the adults, there were 53 women and 13 men. In addition to encephalopathy as required, stroke-like signs presented in 23 (27%) case, seizure in 56 (66%), myoclonus in 32 (38%), and visual hallucination or paranoid delusion in 31 (36%). The course was relapsing and remitting in 51 (60%) of cases.

Laboratory Findings

Also in the series of Rowland and colleagues [90], both Tg and microsomal or TPO antibodies were found together in 60 (71%) cases with one antibody of the two normal in 20 (24%) cases. There was no relationship between the neurologic symptoms and signs and the type or serum concentration of anti-thyroid antibodies. Altogether, 30 (35%) cases were sub-clinically hypothyroid, 19 (22%) were euthyroid, and 17 (20%) were overtly hypothyroid. Fourteen (16%) cases had an elevated erythrocyte sedimentation rate or antinuclear antibody, and three had a concomitant connective tissue disease (psoriatic arthritis, Sjogren's syndrome, and sarcoidosis).

A 19 year-old male with HE and subacute neuropsychiatric complaints and HT recently seen at New York University Langone Health by this author, had HT demonstrated by ultrasound and fine needle aspiration (Figure 1). ¹⁸Fluorodeoxyglucose positron emission tomography (PET) of the brain fused with MRI demonstrated the typical features of autoimmune encephalitis. There was signal abnormality in the left hippocampal tail and hypometabolism in the (mesial) temporal and parietal lobes (Figure 2). Nuclear medicine cerebral perfusion (brain) single photon emission computed tomography (SPECT) showed bilateral temporal and right parietal lobe hypoperfusion.

Figure 1. Hashimoto's thyroiditis. Fine needle aspiration in a Diff-Quik® staining of a goiter in a background of lymphocytic thyroiditis. There is a thin background of purple colloid in between grey staining red blood cells amid follicular cells and dark blue staining nucleated lymphocytes recognized by crush or stringing effects (Magnification 200X).

Figure 2. Hashimoto encephalopathy. Positron emission tomographic imaging (right panel) from the vertex to foramen magnum following injection of 10-mCi 18fluoro-D-glucose is fused with gadolinium-enhanced magnetic resonance imaging (left panel). There is hypometabolism of the medial temporal lobes (asterisks), and signal change in the tail of the hippocampus (arrows).

Cerebrospinal fluid was normal without evidence of infection or another pathogenic autoantibody, apart from TPO. An elevated CSF protein level was noted in 66 (78%) patients, with abnormal findings in neuroimaging in 40/82 (49%) or electroencephalography in 80/82 (98%) patients. A goiter was detected in 24/39 (62%) patients, with a serum microsomal antibodies in 55/58 (95%), TPO antibodies in 26/26 (100%), and Tg antibodies in 45/62 (73%) patients.

Immunopathogenic Mechanisms

Unlike the close relation between anti-thyroid antibodies and thyroiditis in HE, neither high titers of anti-thyroid antibodies nor the presence of subclinical or overt hypothyroidism accounted for the observed encephalopathy in the series of Rowland and coworkers [90]. The neurological findings in patients that were euthyroid were similar to those with subclinical or overt hypothyroidism. Given the lack of a well-defined pathophysiologic link between anti-thyroid antibodies or HT or HE, the term encephalopathy may be a misleading, as the disorder may be one of a larger group of autoimmune encephalopathies. Ochi and colleagues [91] provided a link between HT autoimmunity and the CNS. Using a human brain proteome map and two-dimensional electrophoresis to screen brain proteins reactive to serum antithyroid antibodies, the authors [91] identified α -enolase, a candidate marker for HE-related pathology, encoded on 1p36.23. Kishitani and coworkers [92] extended the findings of Ochi and colleagues [91] noting anti-NH₂-terminal of α -enolase antibodies in 24% of HE patient sera and limbic abnormalities on MRI demonstrating abnormal signal in unilateral or bilateral medial temporal lobes, and diffuse slow wave activity with epileptogenic discharges. These findings suggested that limbic encephalitis- associated with anti-NH₂-terminal of α -enolase antibodies could be a possible manifestation of HE in some cases. Graus and colleagues [3] proposed Hashimoto encephalopathy as an autoimmune encephalopathy or encephalitis after exclusion of other syndromes associated with well-defined autoantibodies. At present, it is unclear whether antithyroid antibodies represent an immune epiphenomenon in a subset of patients with encephalopathy or are truly associated with pathogenic mechanisms of the disorder.

According to Rowland and colleagues [90], one subgroup of patients with HE present with stroke-like episodes. Inoue and colleagues [93] described a patient with progressive Parkinsonism and normal cognitive and intellectual performance. Slow background activity on electroencephalography was the only sign of encephalopathy, which normalized after treatment with corticosteroids. Younger [94] described a patient with hemi-parkinsonism in a stroke-like onset. ¹⁸Fluoro-D-glucose- positron emission tomography metabolic imaging showed severe hypometabolism within the posterior aspect of the left putamen suggesting focal vascular injury, with superimposed left temporal and left parietal hypometabolism and mild volume loss relative to the rest of the brain (Figure 3).

A vasculitic pathogenesis appears to be equally likely in some cases of HE based upon the tendency for increased autoimmunity in HT. In addition, the available histopathology in HE also supports an inflammatory vasculopathy, so noted in one postmortem case that showed lymphocytic infiltration of brainstem veins [95], and in brain biopsy tissue from another case categorized as isolated angiitis due to lymphocytic infiltration of the walls of

arterioles and veins [96]. Brain biopsy tissue of second living patient showed perivascular cuffs of lymphocytic cells [90]. It is noteworthy that patients with HE and circulating α -enolase antibodies are at risk for heightened autoimmune activity, and a tendency for systemic and invasive autoimmune disorders including systemic vasculitis [97, 98].

Figure 3. Hashimoto's encephalopathy. Positron emission tomographic (PET) imaging from the vertex to foramen magnum following injection of 10 mCi ^{18}F -fluoro-D-glucose (left image) shows severely reduced metabolic activity in the posterior half of the left putamen on standard PET imaging, and with fusion to gadolinium-enhanced magnetic resonance imaging (MRI) (right image).

Treatment

The significance of corticosteroid sensitivity in HE is widely accepted as a criterion for the diagnosis. However, as Rowland and colleagues suggested [90], it would be unwise to define any condition by response to any particular therapy especially if not replacing a specific deficit or directing it at a particular target. Patients with HE improve in association with, but not necessarily due to corticosteroid therapy. Moreover, those that respond to corticosteroids have no distinguishing clinical characteristics nor receive treatment in other fashions for a meaningful comparison.

CONCLUSION

There has been a rapid expansion in knowledge of autoimmune encephalitis neurological and neuropsychiatric disorders. Three well-describe disorders targeting antigens on the surface or in the cells of the temporal lobe neuropil manifest limbic and extra-limbic dysfunction. Patients with HT may develop a rare autoimmune encephalopathy. Recognition of these cases have shifted clinical paradigms and led to new insights into the mechanisms of

autoimmune encephalitis. Those with available histopathology show variable humoral and cell-mediated autoimmune, with cytotoxic T-cell inflammation targeting neuropil antigens, making them more similar than not, to primary CNS vasculitis. One important difference however is the more favorable outcome in autoimmune encephalopathy and HE compared to primary CNS vasculitis, making their recognition essential in choosing appropriate immunotherapy to achieve long-lasting remission.

Chapter 225

OVERVIEW OF THE TREATMENT OF PRIMARY SYSTEMIC VASCULITIS

Antoine Sreih, MD and Peter A. Merkel*, MD, MPH

Division of Rheumatology, University of Pennsylvania,
Philadelphia, Pennsylvania, USA

ABSTRACT

Vasculitis is a group of heterogeneous diseases that often involve organ- and life-threatening manifestations. Prior to effective therapy vasculitis had an extremely high mortality. However, the last 3 decades have seen continuous progress and substantial improvements in establishing early diagnosis and effective treatment for these diseases. These major advances are largely due to enhancement in the description and classification of vasculitis, the implementation of standardized outcomes, and the availability of large cohorts and randomized clinical trials due to ongoing collaborative efforts. This chapter will provide an overview of the general concepts of therapy for vasculitis, highlight the importance of randomized trials in establishing standard treatment algorithms for some forms of vasculitis, outline recent advances in the treatment of primary systemic vasculitis, and describe novel approaches being considered to treat the vasculitides.

Keywords: vasculitis, treatment, overview

INTRODUCTION

Primary systemic vasculitides are highly heterogeneous diseases in which inflammation of blood vessels, especially arteries, is the hallmark of the pathophysiology and usually the major source of morbidity for patients. The different forms of vasculitis affect different sized vessels and vary in the processes leading to inflammation, for example immune complex

deposition or granulomatous pathology. These diseases can differ markedly in the predominant organ affected, the clinical manifestations, and the nature of the disease-related damage. Vasculitis ranges from a single-episode of mild annoyance to recurrent life- and organ-threatening disease. Approaches to the treatment of vasculitis can differ greatly and must take into account the great variation in disease type and extent.

Treatment of the primary systemic vasculitides has evolved over the past twenty years from a one-size-fits-all approach to more individualized therapy based on the type and severity of vasculitis. For some cases of vasculitis biomarkers or other prognostic factors affect treatment decisions. The great progress made in treatment of vasculitis is due to several advances that have occurred in parallel, including an increased understanding of disease pathogenesis, establishment of international clinical research networks, increased research funding, development of new drugs to treat autoimmune diseases, and conduct of high-quality, multinational randomized clinical trials (RCTs).

This chapter will describe the underlying concepts guiding treatment of vasculitis, clinical trial standards and individualization of therapy, and outline treatment of several types of vasculitis. Where possible the data presented will be based on clinical trials and other sources of good evidence. Details of treatment can be found in the chapters in this textbook dedicated to specific forms of vasculitis.

GENERAL APPROACH TO TREATMENT OF VASCULITIS

The treatment of primary systemic vasculitis largely depends on the specific type of vasculitis and the extent of organ involvement. Therefore, confirmation of the diagnosis and a comprehensive assessment of disease severity are necessary prior to initiating therapy. It is imperative to know the full extent of disease to both be sure that the level of treatment matches the most severe manifestations present, and to stage the extent of specific manifestations present at the start to therapy to allow for proper reassessment later in the treatment course.

Treatment of systemic vasculitis generally consists of a period of remission induction followed by remission maintenance, and long-term follow-up. The duration of therapy usually depends on the type and severity of vasculitis. Treatment also includes management of specific organ damage, prophylaxis against, and treatment of, medication-related toxicities.

Remission-Induction

Remission-induction is the period lasting from the initiation of treatment to the achievement of remission. The duration of this period is usually 3 to 6 months but may vary based on the severity and type of vasculitis. Some patients never achieve remission but most will achieve either remission or a state of low disease activity. Induction of remission almost always includes treatment with moderate-high doses of glucocorticoids alone or in conjunction with another form of immunosuppression. The most common immunosuppressive agents used for remission-induction of severe forms of vasculitis are cyclophosphamide and rituximab; however, several other agents are also used for induction.

Adjunctive therapies such as plasma exchange, renal replacement therapy, respiratory support, infection prophylaxis, and other interventions may be used during this period depending on the specific type of vasculitis and the presence of organ failure.

Remission-Maintenance

Remission-maintenance is the period that follows induction and is aimed at consolidating remission and preventing relapses. During this period glucocorticoids are tapered off or lowered to the minimum dose possible. If cyclophosphamide is used for remission-induction then during the maintenance phase, cyclophosphamide is replaced by a less toxic immunosuppressive agent. However, when rituximab is used for remission-induction then additional doses are often given for remission-maintenance. The concept of remission-maintenance was initially introduced and demonstrated to be effective in clinical trials of small-vessel vasculitides, notably anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV). A similar approach is now frequently applied to medium-vessel vasculitis such as polyarteritis nodosa (PAN) and Kawasaki disease (KD), and the large-vessel vasculitides including giant cell arteritis (GCA) and Takayasu arteritis (TAK), and other types of vasculitis. The duration of the remission-induction period varies among the vasculitides. For some diseases with a lower probability of relapse, such as PAN, this period may be 12 months while for a disease with frequent relapses, such as granulomatosis with polyangiitis (GPA), remission-maintenance may be much longer. Cogan's syndrome and Behçet's disease are examples of variable-vessel vasculitides and are considered in greater depth elsewhere in this textbook.

Post-Treatment

Even after the remission-maintenance phase of treatment has ended and all immunosuppressive drugs are discontinued, it is imperative that patients are followed regularly for the possibility of disease relapse and to monitor for the occurrence of late-onset medication side effects and cardiovascular events.

RANDOMIZED CLINICAL TRIALS IN THE VASCULITIDES

Since the first curative randomized clinical trial in the history of medicine was conducted in 1946 to study the use of streptomycin in tuberculosis [1] the design and complexity of RCTs steadily evolved to include various study designs, often large number of study subjects, and an emphasis on multicenter studies. The regular conduct of clinical trials to study treatment of vasculitis is only a relatively recent development. The rarity of primary systemic vasculitis, the lack of adequate research funding, the challenges of studying complex heterogeneous disorders, and the small number of academic centers with expertise in these diseases meant clinical research in vasculitis initially consisted of single-center case series and cohort studies, small single-arm and open label trials in a small set of diseases.

The past twenty years has witnessed tremendous progress in the conduct of clinical trials in vasculitis. This progress has occurred due to several factors. First, the widespread adoption of standardized definitions [2, 3] and classification criteria [4, 5] for the vasculitides, leading to greater standardization of eligibility criteria.

Second, the use of validated outcome measures for vasculitis [6-8], although many forms of vasculitis still lack well-validated measures of disease activity or state for use in clinical trials. The Vasculitis Working Group of the Outcome Measures in Rheumatology (OMERACT) initiative is actively pursuing a variety of projects to advance development of valid measures in multiple forms of vasculitis [7, 9-11].

Third, the establishment of national and international research networks including the Vasculitis Clinical Research Consortium (VCRC) (www.RareDiseasesNetwork.org/vcrc), the European Vasculitis Society (EUVAS) (www.vasculitis.org), and the French Vasculitis Study Group (FVSG) (www.vascularites.org). These networks facilitate collaborations between academic institutions with expertise in clinical care and research in vasculitis. Many of the key multicenter trials in vasculitis have been conducted by these groups or the core personnel within the groups. The VCRC and the EUVAS are now conducting several large RCTs together, indicative of the growing international cooperative spirit within the vasculitis research community.

Fourth, the increased funding for clinical trials in vasculitis by governmental agencies, private foundations, and the biopharmaceutical industry, singly or in combination.

Fifth, the rapid growth of patient engagement and patients as research-partners, the close collaboration between various stakeholders, and the use of the Internet as a means of communication, recruitment, and dissemination have revolutionized the way some clinical research is done.

Advances in standardized approaches to conducting clinical trials was demonstrated by the publication in 2007 by a group that included leaders of these networks and other international experts in vasculitis of recommendations for conducting clinical trials in systemic vasculitis [12].

OVERVIEW OF THE TREATMENT OF VASCULITIDES

The treatment of primary systemic vasculitis substantially evolved over the years from extended courses of monotherapy with glucocorticoids to more complex, multi-stage regimens that combine glucocorticoids with additional immunosuppressive drugs. These progressions in therapeutic approach are due to several factors, including the implementation of successful larger randomized clinical trials as outlined above, the availability of targeted therapy with so-called “biologic” therapies, and incorporation of specific disease subtypes and prognostic factors that allow for greater individualization of treatment.

Prognostic Factors

A major advance in the field of vasculitis has been the recognition and data supporting the concept that certain clinical factors are associated with disease course in some forms of

vasculitis and can assist in the choice and duration of therapy. The clinical pattern, disease phenotype, and history of relapse in patients with GPA and microscopic polyangiitis (MPA) are each predictive of prognosis with treatment. Patients seropositive for anti-proteinase 3 ANCA are at substantially higher risk of relapse than patients with anti-myeloperoxidase ANCA [13, 14], while patients with GPA are more likely to relapse than patients with MPA, a finding not surprising given the much higher prevalence of anti-proteinase 3 ANCA among patients with GPA [14]. A history of relapse in AAV is highly predictive of future relapse. Thus, these prognostic factors are taken into consideration when developing a treatment regimen for patients with AAV, including duration of therapy.

The five factor score (FFS), a prognostic tool created by the FVSG [15-17], is another example of how severity and specific organ involvement may serve not only as a prognostic tool, but also help direct the therapeutic choice in systemic necrotizing vasculitis [18, 19]. The FFS is based on the presence of five clinical items: renal insufficiency, proteinuria, central nervous system involvement, cardiomyopathy, and gastrointestinal involvement. Each clinical item is assigned one point with a total maximum of five points. Patients with systemic vasculitis such as PAN, MPA, and eosinophilic granulomatosis with polyangiitis (EGPA) have a 5-year survival of 88% if FFS = 0, 74% if FFS = 1, and 54% if FFS $\geq$ 2 [15]. The FFS, which has only been substantively tested in PAN, MPA, and EGPA, is calculated at the initial presentation, and has been used to help decide among different treatment courses and whether to add another immunosuppressive agent to glucocorticoids for initial treatment of vasculitis [18, 20, 21]. The FFS was revised in 2011 to include GPA. The presence of ear, nose, and throat (ENT) involvement in GPA and EGPA was associated with a reduction in mortality. The revised FFS currently comprises: age $\geq$ 65 years, cardiac involvement, gastrointestinal involvement, renal insufficiency (stabilized peak creatinine $\geq$ 150 μ mol/L), and absence of ENT involvement [16].

The type of vasculitis can also dictate the treatment of primary systemic vasculitis. Some vasculitides, such as PAN and anti-glomerular basement membrane disease are more likely to have a single course of disease without relapse, while other diseases, such as GPA or GCA commonly relapse. Additionally, the severity or type of manifestations may change over time. All of these factors plus individual patient-specific variables are important when considering the treatment options for patients with vasculitis.

TREATMENT OF SPECIFIC VASCULITIDES

The following section will provide outlines on the treatment of specific forms of vasculitis with an emphasis on data derived from controlled clinical trials and will highlight some of the differences in the approach to treatment with the different forms of vasculitis. Many individual patient characteristics and disease variables will impact the decision to adopt and implement any of the treatment regimens described below. The treatment of affected patients with vasculitis should always be directed by physicians with experience in the treatment of vasculitides and the use of immunosuppressive medications. By far the most and highest quality data on treatment of vasculitis is available for GPA and MPA since AAV has been the focus of several large randomized controlled trials. The treatment recommendations

and drug dosages provided below pertain mainly to adults should be appropriately adjusted for use in children.

Glucocorticoids

The treatment of nearly all forms of vasculitis involves the use of glucocorticoids and these agents remain a mainstay of treatment, either as single therapy or as part of combination therapy. For severe disease intravenous pulses are usually given for 1 to 3 days followed by high-dose oral glucocorticoids, for example prednisone 1 mg/kg/day followed by a steadily tapering dose. Less severe disease may be treated initially with lower doses of glucocorticoids and mild flares may be treated with only a small increase in their dose. More recently, a large multinational clinical trial called “Plasma Exchange and Glucocorticoid Dosing in the Treatment of Anti-Neutrophil Cytoplasm Antibody Associated Vasculitis (PEXIVAS)” demonstrated that a reduced cumulative dose of glucocorticoids was as effective for induction of remission and long-term outcomes as the standard higher-dose regimen, with lower rates of infection seen in the lower-dose glucocorticoid arm. Glucocorticoids are usually given for at least 6 months or more after the initial presentation or after a moderate-severe flare. The total duration of therapy with glucocorticoids for vasculitis is controversial with some experts advocating for attempting to get patients fully off glucocorticoids in the first year of treatment and others promoting the extended use of low-dose glucocorticoids in the first 12 to 18 months of treatment [22, 23].

SMALL-VESSEL VASCULITIS

ANCA-Associated Vasculitis: Granulomatosis with Polyangiitis and Microscopic Polyangiitis

The treatment of GPA and MPA has evolved over the last four decades from glucocorticoids alone to extended use of cyclophosphamide [24] to several different treatment protocols based on disease severity, disease stage, and including substantially reduced cumulative doses of cyclophosphamide or the avoidance of this medication altogether [25]. For purposes of treatment, severe disease flare in AAV is generally defined as the presence of active disease manifestations that are organ- and/or life-threatening.

Remission-induction therapy for severe initial presentations or flares and relapses of disease in AAV currently involves the use of glucocorticoids in combination with a choice of cyclophosphamide or rituximab. Two clinical trials compared cyclophosphamide to rituximab for remission-induction and found these two treatments to have similar efficacy in inducing remission when used in combination with glucocorticoids [26, 27]. The standard dose of oral cyclophosphamide for remission-induction of AAV is 2 mg/kg/day for 3 to 6 months. Pulse intravenous cyclophosphamide therapy is a reasonable alternative to oral administration. A randomized trial (the “CYCLOPS” study) demonstrated equivalence of the two routes of administration of cyclophosphamide for remission-induction [28] and the use of intravenous cyclophosphamide is supported by other studies [29]. However, it is important to note that the

dosing of cyclophosphamide per the “CYCLOPS” regimen is 15 mg/kg every 2 weeks for 3 infusions then once every 3 weeks. The duration of cyclophosphamide use in the major trials was 4 to 6 months prior to transition to another agent. The dose of oral or intravenous cyclophosphamide should be adjusted down among patients with renal insufficiency, in response to leukopenia, and in older patients.

Remission-maintenance treatment in AAV following achievement of remission with cyclophosphamide involves the use of intravenous rituximab 500 mg every 6 months. Azathioprine at the dose of 2 mg/kg/day or methotrexate at doses of 20 to 25 mg/week can also be used for at least 1-2 years after cyclophosphamide and often much longer or indefinitely for patients at high risk of relapse [30-32]; one RCT found no difference in the efficacy of azathioprine and methotrexate for maintaining remission [33]. The choice between these two agents depends on individual patient factors and preferences; methotrexate should not be used by patients with renal insufficiency. The IMPROVE trial in AAV [34] showed that following induction of remission with cyclophosphamide, azathioprine was superior to mycophenolate mofetil for remission-maintenance making the latter a third choice for this indication, after azathioprine and methotrexate.

Rituximab was found to be as effective as cyclophosphamide at inducing remission in AAV [26, 27]. The induction regimen used in the trials was 375 mg/m² given intravenously weekly for 4 consecutive weeks. Rituximab is a reasonable alternative to cyclophosphamide for treatment of severe AAV. However, the high cost of this drug has resulted in wide variation internationally in the use of rituximab. In some countries it is a first-line treatment option, especially to treat younger patients seeking to preserve their fertility. In many countries use of rituximab is restricted to patients with relapsing disease, especially those who have had prior courses of cyclophosphamide who comprise a subset of patients for whom rituximab was found superior to cyclophosphamide in the RAVE trial [14]. In other countries rituximab is unavailable as a treatment option.

The appropriate choice of treatment for remission-maintenance following induction of remission with rituximab remains uncertain. In the RAVE trial [14] one course of rituximab was equally efficacious in maintaining remission as 18 months of cyclophosphamide and azathioprine. Single-center retrospective cohort studies provided evidence that repeated doses of rituximab helped maintain remission in many patients [35, 36]. However, due to the expense of rituximab and concerns about the impact of repeated dosing and hypogammaglobinemia, consideration has since been given to using more standard immunosuppressive agents such as azathioprine or methotrexate following rituximab. Different treatment strategies for maintenance of remission in AAV after induction with rituximab are currently being studied in a multinational clinical trial (RITAZAREM) (ClinicalTrials.gov Identifiers: NCT01697267)).

The role of plasma exchange in the treatment of AAV has been highly controversial. In one RCT of patients with AAV and severe rapidly-progressive renal impairment at diagnosis, the addition of plasma exchange reduced the frequency of progression to end-stage renal disease but not overall mortality [37]. Other studies did not clearly demonstrate the benefit of plasma exchange in AAV [38], including for the treatment of alveolar hemorrhage. A recent large multinational, randomized clinical trial involving 704 patients with GPA and MPA (the PEXIVAS trial), treatment of severe AAV in a large m [39] plasma exchange did not reduce the rate of end-stage renal disease or death.

Adjunctive therapy with high-dose intravenous immunoglobulin therapy has been used in patients who fail to achieve remission with standard approaches [40].

The data is mixed on the efficacy of trimethoprim-sulfamethoxazole as treatment for upper respiratory manifestations of AAV or in the maintenance phase of treatment [41-43]. This drug is routinely use for prophylaxis against *pneumocystis jirovecii* pneumonia for patients with AAV receiving immunosuppressive agents.

Two other immunomodulating drugs have shown promise in phase II clinical trials for the treatment of GPA and MPA including abatacept (CTLA4-Ig) for the treatment of non-severe relapsing GPA and an oral inhibitor of C5a (CCX168) for the treatment of GPA and MPA. The results of a phase III clinical trial are expected to provide more definitive data on the utility of the oral inhibitor of C5a (CCX168) for the remission and maintenance of GPA and MPA (ClinicalTrials.gov Identifier: NCT02994927).

The optimal duration of therapy for remission maintenance in GPA and MPA remains unknown. However, the trend has been towards longer courses of therapy with the remission-maintenance agent often continued for at least 12 to 18 months for treatment of new-onset disease and even longer or indefinitely for relapsing disease. Affected patients that demonstrate ANCA with specificity to proteinase 3 have substantially higher rates of relapse than those patients positive for antibodies to myeloperoxidase; relapse in AAV is itself predictive of future relapse [14].

Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss)

The approach to treatment of EGPA differs somewhat from the other AAV due to several factors including recognition that many patients may have a monocyclic course, identification of clinical prognostic factors influencing the choice of treatment, and the impact of recurrent asthma on clinical course.

A recent randomized trial demonstrated that blockade of IL-5 by a monoclonal antibody (mepolizumab) resulted in significantly more weeks in remission and a higher proportion of participants in remission than did placebo, thus allowing for reduced glucocorticoid use in patients with EGPA. This clinical trial led to the first FDA approval for a drug for the treatment of EGPA.

Several other clinical trials conducted in EGPA by the FVSG have provided guidance to treatment of this form of vasculitis; however, these studies have often included a mixture of patients with EGPA, MPA, and PAN making interpretation of results complicated. Glucocorticoids are the mainstay of therapy for EGPA and are included in all treatment regimens and are often the sole treatment for cases without poor-prognosis factors (FFS = 0) [18], or in combination with intravenous cyclophosphamide when the FFS ≥ 1 . In a trial of superiority of six versus twelve pulses of cyclophosphamide (600 mg/m² per pulse) in patients with a poor prognosis, defined as a FFS ≥ 1 , the longer duration of treatment was superior to shorter treatment for control of disease [19]. Patients treated with glucocorticoids alone had more frequent relapses suggesting the need for a revision in this treatment approach. A RCT of azathioprine and glucocorticoids as first-line treatment in EGPA without factors mitigating poor-prognosis demonstrated no additional benefits for remission rates, relapse risk, sparing of glucocorticoids, or diminishing the EGPA asthma/rhinosinusitis

exacerbation rate over glucocorticoids alone. Although the trials of EGPA mainly involve use of intravenous cyclophosphamide, many centers will apply the treatment regimens used for GPA and MPA for patients with severe EGPA and prescribe oral cyclophosphamide for several months, transitioning afterward to azathioprine or methotrexate for remission maintenance. Methotrexate combined with glucocorticoids is another regularly used remission-induction regimens to treat non-severe EGPA [44].

It remains intriguing yet controversial to consider the ANCA status when treating patients with EGPA, include for example, whether patients positive for ANCA should be treated according to strategies for GPA and MPA or whether patients negative for ANCA be treated in a different manner.

Newer agents such as other IL-5 inhibitors (reslizumab [ClinicalTrials.gov Identifier: NCT02947945] and benralizumab [ClinicalTrials.gov Identifier: NCT03010436]) are under investigation for the treatment of EGPA. While rituximab use has been limited to a few case series [45, 46], there is enthusiasm for using rituximab to treat EGPA based on experience with GPA and MPA, especially for patients who test positive for ANCA (ClinicalTrials.gov Identifier: NCT02947945).

The treatment of EGPA is complicated by the presence of asthma in the vast majority of patients. It is controversial whether to consider asthma as a manifestation of vasculitis or a separate aspect of the disease. Asthma is the most common disease manifestation of EGPA and may drive the clinical decision to treat with glucocorticoids, whether prescribed at chronic low maintenance doses or periodically at high-doses to control exacerbations of asthma.

IMMUNE COMPLEX-MEDIATED VASCULITIS

Cryoglobulinemic Vasculitis

The treatment of cryoglobulinemic vasculitis (CV) depends upon the etiology and the severity of associated organ involvement. While antiviral therapies remain the cornerstone of the treatment of hepatitis C virus (HCV)-related CV, glucocorticoids, immunosuppressive drugs, and plasma exchange can all be used for the acute treatment of HCV-associated CV. Two RCTs demonstrated the efficacy of rituximab to treat HCV-related CV with recurrent disease despite anti-viral therapy and standard immunosuppression [47-49]. Rituximab is prescribed in non-HCV-associated CV but data from clinical trials for this indication are lacking. Less severe cases of CV, such as mild skin disease and arthritis, can be treated with a short course of glucocorticoids. Persistent disease with idiopathic CV may necessitate treatment aimed at whatever is presumed to be the underlying plasma cell dyscrasia.

IgA-Vasculitis (Henoch-Schönlein)

IgA-vasculitis (IgAV) is a disease for which the course and treatment may be different between children and adults. The data for treatment of IgAV is derived from a few clinical trials in children and mostly case series for adults. There is neither consensus for the

treatment of IgAV, nor agreement as to whether available therapies change the course of the disease.

MEDIUM-VESSEL VASCULITIS

Polyarteritis Nodosa

In comparison to AAV, there are limited data from clinical trials to support the choice of treatment in PAN [50-52] and the often monocyclic nature of the disease may complicate the determination of risks and benefits any given immunosuppressant regimen. The practice of pooling patients with PAN, MPA, and EGPA within a single clinical trial can make study results difficult to interpret. The treatment of PAN generally follows a type- and severity-based strategy, including utilization of the FFS. Results from uncontrolled studies and expert opinion suggest that the primary treatment of hepatitis B virus (HBV)-associated PAN can be treated with antiviral therapies; however, a short course of glucocorticoids may be appropriate treatment of acute vasculitis-related complications. The role of plasma exchange in HBV-associated PAN remains controversial [53, 54].

The treatment of idiopathic PAN without HBV infection relies on immunosuppressive therapy. For limited cutaneous and mild systemic PAN (FFS = 0) prednisone in doses up to 1 mg/kg/day alone is often sufficient treatment; when the disease is controlled then the glucocorticoid dose is tapered slowly.

The treatment of patients with severe systemic PAN (FFS ≥ 1) associated with involvement of the kidney, heart, gastrointestinal tract, and the central nervous system (CNS) includes combination of high-dose glucocorticoids and another immunosuppressive agent. Pulse intravenous methylprednisolone at the dose of 1000 mg/day for 3 days followed by prednisone 1 mg/kg/day tapered over 6 months is the recommended glucocorticoid regimen. In addition, cyclophosphamide is given orally at a dose of 2 mg/kg/day or intravenously in doses of 600 to 750 mg/m² every 2 to 4 weeks for 6 months with subsequent transition to azathioprine at a dose of 2 mg/kg/day or methotrexate at doses of 20 to 25 mg weekly for remission maintenance [25]. Some centers treat systemic PAN by prescribing glucocorticoids at the outset in combination with azathioprine or methotrexate but without cyclophosphamide.

Kawasaki Disease

Kawasaki disease occurs almost exclusively in young children. Randomized trials have established the standard of treatment that includes aspirin, intravenous immune globulin, and comprehensive cardiac monitoring through centers experienced in the management of this disease [55-57].

LARGE-VESSEL VASCULITIS

There is ongoing controversy and interest in the question as to whether GCA and TAK constitute a single spectrum of large-vessel vasculitis and thus whether their respective treatments should be the same [58-60]. Glucocorticoids remain the mainstay of remission-induction and generally remission-maintenance therapy in both diseases. However, several recent clinical trials have provided evidence of the benefit of other immunosuppressive agents (anti-IL6R and anti-CTLA4) on disease remission and reducing glucocorticoids cumulative dose. Endovascular and surgical interventions may be required to manage the vascular damage leading to stenosis and aneurysm formation that may occur.

Giant Cell Arteritis

The usual starting dose of prednisone for the treatment of GCA ranges from 40 to 60 mg/day for four weeks with a subsequent gradual taper over many months [61]. The exact timing of glucocorticoid withdrawal is controversial with some centers seeking to attempt to withdraw them at six months and others advocating a longer course of low-dose daily prednisone for the first year of treatment. Intravenous pulse glucocorticoids for three consecutive days may be considered initially in cases of acute visual loss [62].

The benefit of tocilizumab, a monoclonal antibody directed against the IL-6 receptor, in combination with prednisone, was demonstrated in two randomized trials to effectively reduce the risk of relapse among patients with GCA compared to treatment with prednisone alone. Based on the results of these trials, tocilizumab was subsequently approved drug by the FDA and EMA for GCA. Abatacept, a CTLA4-IgG1 fusion protein that binds to the CD80/86 molecule and prevents the activation of T-cells, has also been shown in a double-blind RCT to reduce relapse rates in patients with GCA.

Weekly oral methotrexate can be used as a maintenance agent. The role of methotrexate as a glucocorticoid-sparing agent was studied in three RCTs [63-65] demonstrating conflicting results. However, an individual patient-level meta-analysis demonstrated that methotrexate was efficacious in preventing relapses and reducing total glucocorticoid usage [66]. While the overall efficacy of methotrexate in GCA appears to be modest, it is nonetheless frequently used to help avoid excess glucocorticoid use and to treat relapsing disease.

The use of anti-TNF alpha agents for treatment of GCA was studied in three RCTs, each of which failed to demonstrate efficacy for these agents [67-69]. A trial of infliximab also failed to demonstrate efficacy in polymyalgia rheumatic (PMR) [70].

Several other drugs have been proposed for use as glucocorticoid-sparing agents in GCA, including azathioprine, cyclophosphamide, cyclosporine, hydroxychloroquine, and leflunomide but there is no evidence large clinical studies or RCTs to support the use of these agents [71-74].

The results from an analysis of two large retrospective patient series supported the use of low-dose aspirin as adjunctive therapy in GCA to prevent ischemic complications [77, 78]; however, the routine use of aspirin in GCA remains an ongoing controversy.

Among the challenges of conducting RCTs in GCA are the lack of a clear definition of disease activity, the accepted efficacy and low cost of glucocorticoids, the acute nature of the clinical presentation necessitating immediate treatment, and the difficulty older individuals may have in participating in research studies. Nonetheless, there remains an unmet need to find alternative therapies to high-dose or recurrent courses of glucocorticoids in GCA.

Takayasu Arteritis

Only two RCTs have been conducted in TAK. The first was a trial of abatacept plus glucocorticoids vs. glucocorticoids alone for the treatment of TAK that did not demonstrate efficacy of this biologic agent. The second trial tested tocilizumab plus glucocorticoids vs. glucocorticoids alone and this trial had equivocal results but with some data that tocilizumab may help reduce the time to relapse. Treatment approaches for this rare disorder continue to be based instead on case series, expert opinion, and extrapolation from studies in GCA, which may not be an ideal approach. Glucocorticoids are the foundation of therapy for induction or remission in TAK and the dosing regimen is similar to GCA and other vasculitides with initial high-dose oral glucocorticoids followed by a slow taper over several months. Other immunosuppressive therapies, including azathioprine, cyclophosphamide, methotrexate, and mycophenolate mofetil are routinely prescribed in patients with severe disease or in those with recurrent or refractory disease [79]. Although initial case series reported high efficacy from use of anti-TNF-alpha agents, subsequent series demonstrated that these agents, while possibly helpful in some patients, were associated with substantial rates of disease relapse or incomplete remission-induction [80-83]. Initial patient reports of rituximab [84] to treat TAK have been promising, however, larger series with longer follow-up and RCTs are required to evaluate any agent in this chronic relapsing disease.

Surgical Intervention

Both GCA and TAK are associated with a variety of fixed vascular stenosis and aneurysm formation of the aorta and its main branches. Such lesions occur as a result of scarring after inflammation, even when the disease is seemingly well controlled. Aneurysms, once formed, tend to enlarge just as do aneurysms resulting from other etiologies such as hypertension. Patients with large-vessel vasculitis should be considered for surgical intervention to treat severe or functionally-limiting limb ischemia, cerebrovascular insufficiency, renal artery stenosis with associated severe hypertension, expanding aortic aneurysms, and severe cardiac valvular disease. There remains uncertainty regarding the relative efficacy and advisability of angioplasty, stents, and surgical repair for these vascular lesions. Regardless of which form of repair may be considered, the consensus is that particular attention should be given to controlling disease activity in the peri-procedure period [86-88]. Endovascular procedures in patients with vasculitis should be performed in specialized centers with experience with both the procedures and the management of vasculitis [25].

VARIABLE VESSEL VASCULITIS

Cogan's Syndrome

Most patients with Cogan's syndrome are treated with glucocorticoids with a favorable response for both vestibule-auditory and ophthalmologic manifestations. Other therapies, all based on small case series or expert opinion, included methotrexate, cyclophosphamide, azathioprine, anti-TNF alpha agents, hydroxychloroquine, and intravenous immunoglobulin. Surgical cochlear implantation can lead to objective and subjective benefits with improved hearing recognition in the majority of patients.

Behçet's Disease

Behçet's disease is a complex multisystem disorder in which several clinical trials have been conducted using a variety of different outcome measures. However, unlike most trials in other forms of vasculitis where overall disease activity is the outcome of interest, those in Behçet's disease have often focused on specific manifestation such as mucocutaneous lesions and uveitis. A RCT of apremilast for the treatment of oral ulcers in Behçet's disease showed promising results [11] and a larger Phase III has been completed (ClinicalTrials.gov Identifier: NCT02307513). Thus, treatment recommendations are complex and depend upon the stage of disease, sex of the patient, and disease manifestations of greatest concern.

PRIMARY CENTRAL NERVOUS SYSTEM VASCULITIS

There are no RCTs to guide treatment of primary central nervous system vasculitis (CNSV) also known as primary angiitis of the CNS. Treatment is based upon the clinical experience from case series, cohort studies, and expert opinion [89]. The initial treatment of CNSV includes prednisone 1 mg/kg/day often in combination with cyclophosphamide administered in monthly intravenous pulses with later transition to azathioprine, methotrexate, or mycophenolate mofetil for an additional period of 12 to 18 months as remission maintenance. TNF-alpha blocking drugs have been used to treat CNSV refractory to glucocorticoids and other immunosuppressive drugs [90, 91]. The treatment of childhood CNSV is reviewed elsewhere [92].

OTHER SYSTEMIC VASCULITIDES

There are several other types of vasculitis for which treatment is based on small case series and expert opinion when RCTs are unavailable. These vasculitides include anti-GBM disease, relapsing polychondritis, single-organ vasculitis (SOV), drug-induced vasculitis, and other unclassifiable vasculitides.

TREATMENT-RELATED TOXICITY

Much of the morbidity incurred by primary systemic vasculitis results from the treatment, rather than the disease itself. It is essential for physicians and patients to constantly monitor for side effects of drugs and use appropriate measures to minimize or prevent treatment-related complications. A detailed discussion of the proper use of immunosuppressive medications is beyond the scope of this chapter.

LONG-TERM COMPLICATIONS OF VASCULITIDES

Disease-related problems in vasculitis go beyond the acute organ damage that occurs due to active vasculitis. Long-term complications of both the underlying vasculitis and the treatments are increasingly recognized as contributing to the overall morbidity of patients with vasculitis. In addition to the direct damage caused by vasculitis such as renal failure, visual loss, aneurysm, lung impairment, and other problems, it is important to monitor and treat other long-term complications that may be more common with vasculitis but overlooked. These complications include, hypertension from renal insufficiency and renal artery stenosis, accelerated cardiovascular disease thought secondary to chronic inflammation, obesity from often repeated courses of glucocorticoids, malignancy associated with treatment and possible increased incidence of cancer associated with vasculitis, depression and other mood disorders common among patients with serious chronic illnesses, and physical disabilities that impair daily function and work productivity.

CONCLUSION

Despite the substantial progress made in the therapy of primary systemic vasculitis, the treatment of many vasculitides remains a challenge. Dividing therapy into an induction phase and maintenance phase to improve disease control and minimize side effects as well as individualizing medical management based on the severity, type, and prognostic factors have revolutionized the therapy of vasculitis. Multicenter RCTs have answered critical questions regarding the management of several primary systemic vasculitides but data from trials are still lacking for the majority of vasculitides and for treatment of children with vasculitis. The development of research networks including the VCRC, EUVAS, and FVSG, have all greatly facilitated RCTs in vasculitides and fostered collaboration among these networks to produce major new studies. Newer medications and novel approaches are constantly being tested to refine therapy and improve care in vasculitis. The rapid development of targeted immunomodulatory therapies will likely have a substantial positive impact on the treatment of vasculitis. Similarly, discovery and refinement of reliable biomarkers of disease activity, prognosis, and response to treatment, should usher in an era of individualized or personalized therapy for vasculitis.

ABSTRACT

Alzheimer's disease is the most common subtype of dementia, with studies reporting that it makes up somewhere between 50-72% of dementia cases. Symptoms of Alzheimer's include significant episodic memory impairment, behavioural disturbances and psychopathological disturbances. At this moment there is no cure for Alzheimer's disease, so it is therefore important to promote increased awareness by family members, which could result in more conscientious caregivers and better quality of life. An international research group has conducted studies in the young adult population in various locations to estimate the knowledge about Alzheimer's disease. The results indicated that while only 48% of participants believed that they were knowledgeable about the disease, the assessment quiz indicated that 75% turned out to be very

* Corresponding Author's Email: rchow48@uwo.ca.

knowledgeable. This book will present the data from the studies around the different locations.

INTRODUCTION

Dementia is a broad term that includes a variety of disease subtypes, and is very common among those over the age of 65 years old. It can significantly alter the quality of life of affected patients, and when coupled with other medical conditions, can lead to suboptimal patient care as well [1, 2]. This under-management could snowball into a public health disaster with over 560,000 Canadians suffering from dementia, which accounts for \$10.4 billion in annual expenditure, and this statistic is expected to quadruple within the next 50 years [3, 4]. Tools have been developed by healthcare professionals to help improve the quality of care for these patients [5], but it is still far from a perfect solution.

Alzheimer's is the most common subtype of dementia, with studies reporting that it makes up somewhere between 50% to 72% of dementia cases [2, 6, 7]. Symptoms of Alzheimer's include significant episodic memory impairment, behavioural disturbances, and also psychopathological disturbances [6, 8]. With no cure to Alzheimer's on the horizon, increased awareness by family members could result in more conscientious caregivers and better quality of life.

With the frequency of dementia and its subtypes expected to increase in the future, coupled with the fact that there exists an aging population, it is important that young adults are aware of the disease as they will be responsible to care for the elderly population in the future. An original study was conducted among the young adult population in London, Canada [8]. The results indicated that while only 48% of participants believed that they were knowledgeable about the disease, the assessment quiz indicated that 75% turned out to be very knowledgeable. The authors also investigated into whether there were differences in scores between males and females, those under 20 years old and above 20 years old, and those who have a family member affected by the disease and not affected. There only existed differences in scores between males and females, with females proving to be more knowledgeable.

The trend revealed by the study [8] has important implications, in that it informs about the awareness level and even leads to inference about the prevalence of Alzheimer's among the family members of young adults. The studies contained herein looked to further examine the awareness level of young adults with respect to Alzheimer's disease at different geographical locations around the world.

Chapter 227

AWARENESS OF ALZHEIMER'S DISEASE: ABOUT THE SURVEY AND SURVEY INSTRUMENT

***Ronald Chow**, BSc(C), *Michael Borean*, BSc(C)
and Drew Hollenberg, BSc(C)**

Infinitas Research Group, London, Ontario, Canada

ABSTRACT

Infinitas Research Group, headquartered out of London, Canada, designed a survey with the aim to assess perceived awareness level and actual awareness level of young adults – the age cohort which will be most heavily relied on in the coming decade to care for patients with Alzheimer's disease. The primary objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). The secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

INTRODUCTION

Dementia and its subtypes, such as Alzheimer's, is expected to increase over the next several decades. Given that there is no cure, the best means of management available today is to increase awareness of relatives and family members to hopefully have more conscientious caregivers (see Chapter 1).

Infinitas Research Group, headquartered out of London, Canada, designed a survey with the aim to assess perceived awareness level and actual awareness level of young adults – the age cohort which will be most heavily relied on in the coming decade to care for patients with

* Corresponding Author's Email: rchow48@uwo.ca.

Alzheimer's disease. The objective was to deploy the survey around the globe and assess awareness levels based on geography, age, sex, and familial ties to the disease.

SURVEY QUESTIONNAIRES

A survey was designed to evaluate the awareness of young adults (see Figures 1-4). The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form (see Figure 1). After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex (see Figure 2). The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease (see Figure 3). The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative (see Figure 4).

The primary objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). The secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

STATISTICAL ANALYSIS

Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

Awareness of Alzheimer's Disease

INFORMED CONSENT TO PARTICIPATE IN A RESEARCH STUDY

Principal Investigator: Ronald Chou

Infotrac Research Group

Lindor, ON, Canada

info@researchgroup.ca

<http://sites.google.com/view/info@researchgroup/about-us>

INFORMED CONSENT

You are being asked to consider participating in a research study. A research study is a way of gathering information on something that is not well understood.

Participating in this study is your choice (voluntary). You have the right to choose not to participate, or to stop participating in this study at any time.

INTRODUCTION

You are being asked to consider participating in this study because you are a young adult.

WHY IS THE STUDY BEING DONE?

Dementia and Alzheimer's is being ever more prevalent in the today's society, with the younger generation being relied on more to support those who suffer the debilitating illness. The purpose of this study is to investigate the current awareness and knowledge surrounding Alzheimer's disease among young adults.

BENEFITS AND COSTS

There are no direct benefits or costs to participating in the study. The results from this survey may be published in a manuscript, and benefit the scientific community.

HOW WILL MY INFORMATION BE SECURED?

The study is anonymous, and therefore no names or personal information will be involved in the process.

WHAT ARE THE RIGHTS OF PARTICIPANTS IN A RESEARCH STUDY?

You have the right to receive all information that could help you make a decision about participating in this study. You also have the right to ask questions about the study and your rights as a research participant, and to have them answered to your satisfaction, before you make any decision. You also have the right to ask questions and to receive answers throughout this study.

If you have any questions about this study you may contact the person in charge of this study, the Principal Investigator.

DOCUMENTATION OF INFORMED CONSENT

Participant:

By consenting to this form, I confirm that:

- ☐ I have been fully informed of the risks and benefits of participating in this research study.
- ☐ I have been informed of the rights of research participants.
- ☐ I have been informed of any alternatives to participating in this research study.
- ☐ I have been informed of the rights of research participants.
- ☐ I have this form in its entirety.
- ☐ I have agreed, or agree to allow the person I am responsible for, to participate in this research study.

A copy of your responses will be sent to your email address. The researchers will not be able to match your email address to your responses. If you would not like a copy of your responses sent to your email, feel free to fill in the "Email address" field with info@researchgroup.ca.

¹Infinitas Research Group, London, Ontario, Canada

²Alzheimer's Western Club, London, Ontario, Canada

ABSTRACT

Alzheimer's disease is the most common subtype of dementia, with studies reporting that it makes up over 50% of dementia cases. Lack of awareness has often resulted in failing to diagnose dementia at its early-onset and perhaps failing to slow its deterioration. Better awareness could also be an asset for primary caregivers of individuals suffering from dementia - more knowledge and awareness could lead to better and more attentive quality of care delivered by caregivers. The aim of this study was to determine how knowledgeable young adults are about Alzheimer's disease in London, Canada. A survey was designed to evaluate the awareness of young adults in London, Ontario, Canada, with five quiz questions. Subgroup analyses were conducted to compare scores based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). A total of 79 people completed the survey; 48% of them believed that they were knowledgeable about Alzheimer's disease, 35% reserved judgement, and 16% admitted that they did not know much about the disease. 31% of young adults have a family member affected by Alzheimer's disease. 75% of the young adult population are knowledgeable about the prevalent disease, and only 8% have extremely poor awareness. These findings indicate that young adults seem to be adequately aware of the disease and its implications. Future studies should look into verifying this study in other locations, and also look into whether young adults know how to care for these Alzheimer's patients.

INTRODUCTION

Dementia is very common in those over 65 years of age and affects the quality of life of those afflicted; for long-term care (LTC) elderly residents, it substantially alters their quality of life (QoL) [1, 2]. For LTC residents, dementia coupled with other medical conditions leads to below-optimal QoL and suboptimal patient care [1]. For example, 80% of those residing in LTC suffer from pain but cannot properly verbalize their symptoms as a result of dementia - their pain is frequently underreported and undertreated, although many pain assessment tools have been constructed and validated [1, 3].

Alzheimer's disease is the most common subtype of dementia, with studies reporting that it makes up over 50% of dementia cases [2, 4]. It has been found however that the behavioural and psychopathological disturbances caused by dementia are universal across most subtypes [4]. Lack of awareness of these types of dementia, however, have often resulted in failing to diagnose dementia at its early-onset and perhaps failing to slow its deterioration [5]. Increasing awareness could also be an asset for primary caregivers of individuals suffering from dementia - more knowledge and awareness could lead to better and more attentive quality of care delivered by caregivers [3]. The aim of this study was to determine how knowledgeable young adults are about Alzheimer's disease in London, Canada.

OUR STUDY

A survey was designed to evaluate the awareness of young adults in London, Ontario, Canada, see chapter 2 [6]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [6]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [6]; only those who recorded London, Canada, as their place of residence was included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [6]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [6].

The primary objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). The secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False;

Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

FINDINGS

A total of 79 people completed the survey. 48% of them believed that they were knowledgeable about Alzheimer's disease, 35% reserved judgement, and 16% admitted that they did not know much about the disease. 80% correctly recognized that Alzheimer's disease is a form of dementia, with 9% answering incorrectly and 11% choosing not to use a binary response. Only 8% incorrectly believed that Alzheimer's is part of the normal aging process; 5% recognized they did not know the answer, while 87% correctly responded to the question.

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 79)
Self-belief of being knowledgeable	
Yes	38 (48%)
Neutral	28 (35%)
No	13 (16%)
Alzheimer's is a subtype of dementia	
True	63 (80%)
False	7 (9%)
Not Sure	9 (11%)
Alzheimer's is normal with respect to aging	
True	6 (8%)
False	69 (87%)
Not Sure	4 (5%)
Alzheimer's worsens over time	
True	75 (95%)
False	0 (0%)
Not Sure	4 (5%)
No cure to Alzheimer's	
True	72 (91%)
False	0 (0%)
Not Sure	7 (9%)
Alzheimer's is leading cause of death	
True	30 (38%)
False	25 (32%)
Not Sure	24 (30%)
Overall Score	
Poor (1-2)	6 (8%)
Satisfactory (3)	14 (18%)
Knowledgeable (4-5)	59 (75%)

Almost all (95%) participants acknowledged that Alzheimer's worsens over time, with the other 5% acknowledging they were unsure. 91% correctly believed that there was no cure to Alzheimer's disease, with the remaining 9% not choosing a binary option.

There was no definitive majority answer in response to the statement "Alzheimer's is a leading cause of death" - while 38% correctly agreed with the statement, 32% incorrectly disagreed, and 30% admitted they were unsure. Overall, 75% of individuals were knowledgeable (had 4 or 5 correct questions), while 18% had satisfactory awareness and only 8% with poor understanding of the disease (see Table 1).

Table 2. Awareness of young adults by age

Evaluation Metric	Under 20 Years Old (n = 41)	20 Years Old and Older (n = 38)	p-value
Self-belief of being knowledgeable			0.9104
Yes	20 (49%)	18 (47%)	
Neutral	15 (37%)	13 (34%)	
No	6 (15%)	7 (18%)	
Alzheimer's is a subtype of dementia			0.9210
True	33 (80%)	30 (79%)	
False	4 (10%)	3 (8%)	
Not Sure	4 (10%)	5 (13%)	
Alzheimer's is normal with respect to aging			0.9999
True	3 (7%)	3 (8%)	
False	36 (88%)	33 (87%)	
Not Sure	2 (5%)	2 (5%)	
Alzheimer's worsens over time			0.9999
True	39 (95%)	36 (95%)	
False	0 (0%)	0 (0%)	
Not Sure	2 (5%)	2 (5%)	
No cure to Alzheimer's			0.7053
True	38 (93%)	34 (89%)	
False	0 (0%)	0 (0%)	
Not Sure	3 (7%)	4 (11%)	
Alzheimer's is leading cause of death			0.5597
True	18 (44%)	12 (32%)	
False	12 (29%)	13 (34%)	
Not Sure	11 (27%)	13 (34%)	
Overall Score			0.9999
Poor (1-2)	3 (7%)	3 (8%)	
Satisfactory (3)	7 (17%)	7 (18%)	
Knowledgeable (4-5)	31 (76%)	28 (74%)	

Under 20 Years Old vs 20 Years Old and above

There was no difference between the groups with respect to self-belief about awareness - 49% of those under 20 years old and 47% of those 20 years old and above believed they were well-aware ($p = 0.9104$). 80% and 79% of those under 20, and 20 and above, respectively, acknowledged that Alzheimer's is a subtype of dementia ($p = 0.9210$). The two age groups similarly believed that Alzheimer's is not part of the normal aging process ($p = 0.9999$), that

there is indeed no cure to Alzheimer's disease ($p = 0.7053$), and that it is a leading form of death ($p = 0.5597$). Those 20 years and above, and under 20 years old, had similar overall scores ($p = 0.9999$); 76% of the younger group and 74% of the older group were well-aware about the disease (see Table 2).

Males vs Females

Males and females had similar self-beliefs about their level of knowledge ($p = 0.9441$), with 48% of males and 49% of females stating that they are well-aware of the disease. 82% of females and 76% of males correctly recognized that Alzheimer's disease is indeed a subtype of dementia ($p = 0.7188$), while 81% of males and 89% of females agreed that Alzheimer's is not part of the normal aging process ($p = 0.3734$). The majority of both men (95%) and women (96%) recognized that Alzheimer's worsens over time ($p = 0.9999$). While only 81% of males recognized that there was no cure for Alzheimer's disease, a much higher proportion of females (96%) similarly recognized that ($p = 0.0419$). 24% and 44% of males and females, respectively, correctly answered that Alzheimer's is a leading cause of death ($p = 0.2500$). Overall, females were more knowledgeable than men ($p = 0.0408$) - 82% of females completed the quiz with a score of 4 or 5 out of 5, while only 57% of males received a similar score (see Table 3).

Table 3. Awareness of young adults by sex

Evaluation Metric	Male (n = 21)	Female (n = 57)	p-value
Self-belief of being knowledgeable			0.9441
Yes	10 (48%)	28 (49%)	
Neutral	7 (33%)	20 (35%)	
No	4 (19%)	9 (16%)	
Alzheimer's is a subtype of dementia			0.7188
True	16 (76%)	47 (82%)	
False	2 (10%)	5 (9%)	
Not Sure	3 (14%)	5 (9%)	
Alzheimer's is normal with respect to aging			0.3734
True

Overall Score			0.0408
Poor (1-2)	3 (14%)	2 (4%)	
Satisfactory (3)	6 (29%)	8 (14%)	
Knowledgeable (4-5)	12 (57%)	47 (82%)	

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 24)	Not Affected (n = 54)	p-value
Self-belief of being knowledgeable Yes Neutral No	16 (67%) 6 (25%) 2 (8%)	22 (41%) 21 (39%) 11 (20%)	0.1105
Alzheimer's is a subtype of dementia True False Not Sure	20 (83%) 2 (8%) 2 (8%)	43 (80%) 5 (9%) 6 (11%)	0.9999
Alzheimer's is normal with respect to aging True False Not Sure	2 (8%) 20 (83%) 2 (8%)	4 (7%) 48 (89%) 2 (4%)	0.7359
Alzheimer's worsens over time True False Not Sure	24 (100%) 0 (0%) 0 (0%)	51 (94%) 0 (0%) 3 (6%)	0.5486
No cure to Alzheimer's True False Not Sure	22 (92%) 0 (0%) 2 (8%)	50 (93%) 0 (0%) 4 (7%)	0.9999
Alzheimer's is leading cause of death True False Not Sure	13 (54%) 4 (17%) 7 (29%)	17 (31%) 21 (39%) 16 (30%)	0.0966
Overall Score Poor (1-2) Satisfactory (3) Knowledgeable (4-5)	2 (8%) 2 (8%) 20 (83%)	3 (6%) 12 (22%) 39 (72%)	0.3484

Affected vs Not Affected

There seems to be a trend that those who have a family member with Alzheimer's disease believe that they are more knowledgeable about the illness ($p = 0.1105$), with 67% compared to 44% claiming that they are more knowledgeable. There was no difference in knowledge about whether Alzheimer's is a subtype of dementia ($p = 0.9999$) - 83% and 80% of those affected and not affected, respectively, recognized Alzheimer's as a subtype. 89% of those without family members affected answered that Alzheimer's is not part of the normal aging process, compared to 83% for those affected by Alzheimer's disease ($p = 0.7359$). All (100%) and 94% of those affected and not affected correctly answered that the illness worsens over time ($p = 0.5486$). About 92-93%, in both groups, responded that there is no cure for Alzheimer's disease ($p = 0.9999$). There was a slight indication that those with family members affected by Alzheimer's more likely recognized it as a leading cause of death ($p = 0.0966$; 54% vs 31%). There was no difference in the overall score between the two groups ($p = 0.3484$), with 83% and 72% of those affected and not affected, respectively, correctly answering 4 or 5 questions (see Table 4).

DISCUSSION

This is the first study to our knowledge that looks to evaluate the awareness and knowledge of the general population with respect to Alzheimer's disease. Despite the fact that only 48% of young adults believe they are knowledgeable, it is reassuring to see that a vast majority, 75%, of young adults in London, Canada, are in fact well aware. Hopefully these high awareness levels will matriculate into better chances to diagnosing early-stage Alzheimer's when this cohort becomes of age, and brings the attention to their healthcare professionals at the first sign of symptoms.

Female young adults were more knowledgeable than male young adults about the disease, however. This may be a result of the culture/sex-role stereotypes developed in Canada, where daughters and granddaughters more frequently visit their relatives with Alzheimer's when compared to sons and grandsons, and hence would be more knowledgeable. However, when comparing the knowledge scores between those with family members affected by Alzheimer's disease and those not affected, it seems this may not be the case. Knowledge about the disease did not seem to be dependent on whether a family member has the disease. The difference in knowledge between the sexes may then simply be accounted for by this cohort of female's greater desire to educate themselves about this unfortunate disease.

The study also revealed the proportion of the general population who has a family member affected by Alzheimer's. According to this study, 31% of young adults know of a relative who is/has been affected by the disease. This proportion is fortunately lower than the awareness level; young adults hence seem to be adequately aware of the disease and some of its implications.

This study was not without limitations. The sample size of the study had good quality and quantity at times, but only lead to detection of trends rather than significant differences at other points - a large sample size would have mitigated this issue. A large sample size could perhaps been accrued should the study have been designed without the need to enter an email address, based on the researchers' personal interactions with the population and based on past experience [7-9]. Additionally, due to the nature of the quiz (online survey), there exists the possibility that participants could have employed reference resources to assist in their answers - this is unfortunately unavoidable due to the medium of the survey, but was hopefully minimized by assuring participants that the quiz is an assessment of knowledge and should be answered honestly without help.

In conclusion, this study revealed that 31% of young adults have a family member affected by Alzheimer's disease. 75% of the young adult population are knowledgeable about the prevalent disease, and only 8% have extremely poor awareness. These findings indicate that young adults seem to be adequately aware of the disease and its implications. Future studies should look into verifying this study in other locations, and also investigate whether young adults know how to care for these Alzheimer's patients.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

Infinitas Research Group, London, Ontario, Canada

ABSTRACT

A study recently completed among young adults in London, Canada, surveyed 79 young adults about their awareness of Alzheimer's disease. While only 48% of participants believed that they were knowledgeable about the disease, the assessment quiz indicated that 75% turned out to be very knowledgeable. The aim of this survey is to evaluate whether there is a difference in awareness for those young adults in Kingston, Ontario, Canada. A survey was circulated to young adults in Kingston and completed by 45 individuals. 38% of participants had a family member affected by Alzheimer's disease, to their knowledge. While only 58% believed they were knowledgeable about the disease, it turns out that 80% were in fact knowledgeable. Young adults seem to be well-aware with respect to the disease, and this high level of awareness hopefully will matriculate into better caregivers as these young adults mature and play a greater role in caring for family members afflicted by the disease.

INTRODUCTION

Dementia can be debilitating to patients, and could lead to lower quality of life and less-than-ideal patient care [1]. This may be a result of their difficulty to verbalize their struggles

* Corresponding Author's Email: rchow48@uwo.ca.

[2]. One solution to improve patient care would be to increase the awareness and knowledge of caregivers, so that they can hopefully predict struggles and provide the best care possible.

Alzheimer's disease, which is the most common subtype, has been found to have behavioural and psychopathological disturbances [3]. A study recently completed by Chow et al. among young adults in London, Canada, surveyed 79 young adults about their awareness of Alzheimer's disease [4]. While only 48% of participants believed that they were knowledgeable about the disease, the assessment quiz indicated that 75% turned out to be very knowledgeable. The group also investigated into whether there were differences in scores between males and females, those under 20 years old and above 20 years old, and those who have a family member affected by the disease and not affected. There only existed differences in scores between males and females, with females proving to be more knowledgeable [4].

The aforementioned study surveyed a small cohort in a certain geographic area, but yielded very interesting results. The aim of this survey is to evaluate whether there is a difference in awareness for young adults in Kingston, Ontario, Canada.

OUR SURVEY

A survey was circulated to young adults in Kingston, Ontario, Canada, and was designed to evaluate the awareness of Alzheimer's disease, see chapter 2 [5]. A consent form was put on the first page - there was a field to enter an email for participants to receive a copy of the consent form, should they have desired [5]. Participants had to complete three demographic questions on the second page [5]; only those who resided in Hamilton, Canada, was included in this study. The third page had six questions, designed to evaluate the knowledge of participants with respect to Alzheimer's disease [5]. The final page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [5].

Similar to a prior study conducted [4], the primary objective was to determine the awareness of Alzheimer's disease of all young adults. The secondary objectives were to determine whether there existed any difference in knowledge between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

An overall score out of 5 was generated for each person for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Those who scored 0, 1 or 2 had poor awareness, those with a score of 3 had satisfactory knowledge, and those with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease.

Descriptive statistics were used to report the six question items on page 3. Subgroup analyses were conducted based ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted as part of the subgroup analyses to evaluate whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

OUR FINDINGS

A total of 45 people consented and completed the study. Just over half (58%) believed that they were knowledgeable about Alzheimer's disease; 36% reserved judgement and 7% acknowledged that they were not knowledgeable about Alzheimer's disease. 84% of participants correctly answered that Alzheimer's is a subtype of dementia, with 9% incorrectly responding false and 7% acknowledging they are not sure. Only 3 people (6%) answered incorrectly or admitted a knowledge deficit with respect to Alzheimer's disease and the aging process. All 45 participants correctly answered that Alzheimer's worsens over time, while 96% correctly recognized that there is no cure to Alzheimer's disease. 42% incorrectly believed that Alzheimer's disease is not a leading cause of death, with only 27% of responders correctly answering the question. 80% of young adults scored 4 or 5 out of 5, while 18% scored 3 out of 5 and only 2% received a score between 0 and 2 out of 5 (see Table 1).

Under 20 Years Old vs 20 Years Old and above

Of the 45 participants, 22 were under the age of 20 years old and 23 were 20 years of age and older. 55% of those under 20 years old believed that they were knowledgeable, while 61% of those 20 years and older had a similar belief ($p = 0.9025$). 90% and 83% of the two groups, respectively, correctly believed that Alzheimer's is a subtype of dementia ($p = 0.7991$).

There was no difference between the two groups with respect to the question about Alzheimer's disease and normal aging ($p = 0.7385$); 90% of those under 20 years old and 96% of those 20 years and older correctly responded that Alzheimer's is not part of the normal aging process. All young adults, regardless of age, correctly believe that Alzheimer's worsens over time ($p = 0.9999$). While 90% of those under 20 years old correctly identified that there is no cure to Alzheimer's, all of those 20 years and older similarly responded ($p = 0.2333$). Both groups seemed to be equally-unsure about whether Alzheimer's is a leading cause of death ($p = 0.8666$), with only 45% and 39% of those under 20 and over 20, respectively, correctly answering the question. 14% and 13% of the two groups, respectively, had a satisfactory score, whereas 82% and 87% of the same two groups were knowledgeable according to the five-point score ($p = 0.8283$) (see Table 2).

Males vs Females

1 responder did not identify as male or female; 5 identified as male and 39 identified as female. There was no difference with respect to self-belief between the two genders ($p = 0.9999$), with 60% of males and 59% of females believing that they are knowledgeable. There seems to be a trend that females were more aware that Alzheimer's disease is a subtype of dementia ($p = 0.1300$), with 90% of females correctly answering the question compared to 60% of males. 80% of males correctly answered that Alzheimer's is not normal with respect to aging, while 95% of females similarly answered so ($p = 0.3100$).

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 45)
Self-belief of being knowledgeable	
Yes	26 (58%)
Neutral	16 (36%)
No	3 (7%)
Alzheimer's is a subtype of dementia	
True	38 (84%)
False	4 (9%)
Not Sure	3 (7%)

Alzheimer's is leading cause of death True False Not Sure	3 (60%) 1 (20%) 1 (20%)	9 (23%) 17 (44%) 13 (33%)	0.2981
Overall Score Poor (0-2) Satisfactory (3) Knowledgeable (4-5)	1 (20%) 0 (0%) 4 (80%)	0 (0%) 7 (18%) 32 (82%)	0.1351

All responders of both groups responded that Alzheimer's does indeed worsen over time ($p = 0.9999$). There was no difference between males and females with respect to the answer about the cure for Alzheimer's ($p = 0.9999$) - 100% and 95%, respectively, answered that there is no cure for Alzheimer's disease. While 33% of females responded that they were unsure about whether Alzheimer's is a leading cause of death, only 20% of males similarly responded so ($p = 0.2981$). 80% of males and 82% of females received a score that led to an inference of them being knowledgeable about the disease ($p = 0.1351$) (see Table 3).

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 17)	Not Affected (n = 28)	p-value

Satisfactory (3)	5 (29%)	3 (11%)	
Knowledgeable (4-5)	12 (71%)	24 (86%)	

Affected vs Not Affected

Of the 45 participants, 28 do not have a family member affected by Alzheimer's disease, to their knowledge. Those without familial ties to Alzheimer's are more likely to adopt a neutral stance on their belief about their knowledge - 39% compared to 12% reserved judgement ($p = 0.0186$). Of those affected and not affected by Alzheimer's disease, 82% and 86% respectively correctly acknowledged that Alzheimer's is a subtype of dementia ($p = 0.8317$). 94% and 93% respectively correctly responded that Alzheimer's is not normal with respect to aging ($p = 0.2883$). All participants answered that Alzheimer's worsens over time ($p = 0.9999$). Those not affected by Alzheimer's disease seemed to answer the question about cure to Alzheimer's disease better ($p = 0.1373$), with 100% of those not affected correctly

answering. Those affected by Alzheimer's disease more frequently responded that Alzheimer's is not a leading cause of death (59% vs 32%) as opposed to simply admitting they were unsure (18% vs 39%) ($p = 0.1675$). 29% and 11% of those affected and not affected, respectively, had a satisfactory score of 3 out of 5, while 71% and 86% respectively scored 4 or 5 out of 5 ($p = 0.2262$) (see Table 4).

DISCUSSION

This study validates a finding by Chow et al. conducted amongst young adults in London, Ontario, Canada [4]. The study in London showed that while only 48% of young adults believe they are knowledgeable, a surprisingly higher proportion (75%) turned out to be knowledgeable. This study reveals that young adults in London may be slightly more confident in their knowledge (58%), but that seems to be in line with a larger proportion being knowledgeable (80%). The high level of awareness would hopefully allow for better caregivers, as these young adults mature and have more family members afflicted by the disease.

The subgroup analyses of this study verified the original study [4] that there is no difference in knowledge between those under 20 years old and those 20 years old and older, as well as those with and without family ties to Alzheimer's disease. This study, however, did not find any differences in knowledge between the genders. It is important to note however that only 5 males answered the survey, hence making it difficult to find any noticeable difference in knowledge between the two groups.

The results also revealed that 17 of the 45 participants (38%) have a family member affected by Alzheimer's disease, to their knowledge. This has slightly higher than the 31% reported by Chow et al. among young adults in London, Canada [4].

This study was not without limitations. The sample size of the study had good quality and quantity at times, but only lead to detection of trends rather than significant differences at other points - a large sample size would have mitigated this issue. Additionally, a larger sample of males would have allowed for a better subgroup analyses between genders. Additionally,, there exists the chance that participants could have "cheated" and searched up the answers using reference material. This was hopefully minimized by requesting participants to answer the questionnaire honestly without any aid.

In conclusion, 38% of participants had a family member affected by Alzheimer's disease, to their knowledge. While only 58% believed they were knowledgeable about the disease, it turns out that 80% were in fact knowledgeable. Young adults seem to be well-aware with respect to the disease, and this high level of awareness hopefully will matriculate into better caregivers as these young adults mature and play a greater role in caring for family members afflicted by the disease.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

Alzheimer's disease accounts for the majority of dementia subdiagnoses. Increased awareness of the disease and its consequences may lead to early detection of Alzheimer's symptoms, resulting in earlier diagnosis and better patient outcomes. A recent study determined that the majority of young adults in London, Canada were knowledgeable about the disease. The aim of this study was to determine if these findings generalize to young adults in Toronto, Canada. A survey consisting of five quiz questions equivalent to that utilized in the London study was completed by young adults in Toronto to evaluate awareness levels. Subgroup analyses were conducted to compare scores based on participants' ages (under 20 years old, and 20 years old or older), sex, and family history with Alzheimer's (affected and not affected). 156 people completed the survey; 40% of them believed they were knowledgeable about the disease, and 39% of them had an affected family member. 60% of participants were knowledgeable about the disease, and only 10% were poorly informed. Sex differences in awareness levels exist; 65% of females were knowledgeable compared to 46% of males. Future research should aim to investigate the underlying reasons for these differences. Only 22% of all participants correctly identified that Alzheimer's disease is a leading cause of death; therefore future awareness campaigns should emphasize the high mortality rate associated with Alzheimer's. Overall, this study suggests that young adults in Toronto are generally knowledgeable about Alzheimer's disease.

INTRODUCTION

There are currently over 560,000 Canadians living with dementia, amounting to Canadians spending over \$10.4 billion annually on dementia patient care [1]. Perhaps even more concerning is that there is a steady upward trend in dementia prevalence; studies indicate that prevalence rates could quadruple within the next 50 years [2]. Dementia is often coupled with other comorbidities and results in subpar quality of life and patient care [3]. While many pain assessment tools have been constructed and validated, pain associated with dementia is often under-reported and undertreated [3, 4].

Dementia is an umbrella term that describes a wide range of disease subtypes. The most common form of dementia is Alzheimer's disease. In a study of 474 patients presenting with dementia, an astounding 72% of patients received an Alzheimer's subdiagnosis [5]. Certain pre-clinical symptoms of Alzheimer's, including significant episodic memory impairment, are common in most manifestations of the disease [6]. Increased awareness of the disease and its consequences may lead to early detection of these symptoms, resulting in an earlier diagnosis and better patient outcomes [7]. While Alzheimer's has no cure, increased awareness could be a viable resource for caregivers of individuals with Alzheimer's, as more knowledge of the disease might translate to more conscientious care by caregivers [4].

A recent study by Chow et al. examined awareness of Alzheimer's disease among young adults in London, Canada. Its findings suggested that up to three-quarters of young adults were adequately aware of the disease and its implications, while less than 10% of young adults had extremely poor awareness [8]. The aim of this study was to determine if these findings generalize to young adults in Toronto, Canada.

OUR STUDY

A survey was designed to evaluate the awareness of Alzheimer's disease of young adults in Toronto, Ontario, Canada, see chapter 2 [9]. This survey was identical to the survey utilized by Chow et al. in London, Canada [8]. A consent form was included on the first page of the survey; participants had the option to have a copy of the consent form emailed to them [9]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [9]. Only those who recorded Toronto, Canada, or other locations in the Greater Toronto Area as their place of residence were included in this study. The third page had six questions, with the first being a reflection question regarding the participant's metacognition of Alzheimer's, and the next five comprising a knowledge-based quiz about Alzheimer's disease [9]. The final page of the survey asked participants if they have or had a family member who has been directly affected by Alzheimer's. For participants who have or had a family member affected by the disease, it also asked how often they visit or visited their relative.

The primary objective of the survey was to determine the awareness of Alzheimer's disease, across young adults in Toronto, regardless of other demographics. The secondary objectives were to determine whether there existed any difference in overall disease knowledge between different subgroups, including between males and females, between

younger and older young adults, and between those with and without family members affected by Alzheimer's disease.

Statistical Analysis

Descriptive statistics were used to report the six items (1 reflection question and 5 knowledge questions) on page 3. For each participant, an overall score out of 5 was generated for the number of knowledge-based questions they correctly answered. The answer key is as follows: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's, only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be generally knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

THE FINDINGS

A total of 156 individuals completed the survey. 40% of them believed they were knowledgeable about the disease, 46% reserved judgement, and 13% felt that they were ill-informed about Alzheimer's. 79% of individuals correctly identified that Alzheimer's disease is a subtype of dementia, with 8% answering incorrectly, and a further 13% admitting being unaware. Only 10% of participants incorrectly answered that Alzheimer's disease is a normal part of the aging process, while a promising 83% correctly identified that this is not true. A further 8% were not sure if Alzheimer's disease is normal with respect to aging. The vast majority (91%) of participants were aware that Alzheimer's disease worsens over time, with only 2% and 7% of individuals incorrectly identifying this as false or choosing not to select a binary response, respectively. 88% of participants correctly identified that Alzheimer's disease has no cure, while only 1% incorrectly answered this question, and 11% identified that they were unsure. Interestingly, 42% of participants were unsure if Alzheimer's is a leading cause of death; only 22% correctly identified that this statement is true, while 37% of individuals incorrectly answered that this statement is false. Overall, 60% of individuals were relatively knowledgeable about Alzheimer's disease (answered at least 4 of 5 questions correctly), 30% had satisfactory knowledge (answered 3 of 5 questions correctly), and 10% of participants have relatively poor awareness of Alzheimer's and its implications (10%) (see Table 1).

Knowledgeable (4-5)	93 (60%)

Under 20 Years Old vs 20 Years Old and above

There was no statistically significant difference between age groups in terms of self-belief of knowledge of Alzheimer's disease; 37% and 48% of participants aged under 20 years old and aged 20 years old or older respectively indicated that they felt knowledgeable about the disease ($p = 0.3588$). Identical proportions (79%) of individuals in both age groups correctly recognized that Alzheimer's disease is a form of dementia ($p = 0.3025$). The two age groups also similarly acknowledged that Alzheimer's disease is not normal with respect to the aging process ($p = 0.5947$), that Alzheimer's worsens over time ($p = 0.6297$), and that there is no cure for Alzheimer's ($p = 0.6167$). Both groups were equally ill-informed that Alzheimer's is a leading cause of death; only slightly more than 20% of individuals in both age groups correctly identified the mortality associated with the disease ($p = 0.9054$). There was no difference between overall knowledge scores of the two groups ($p = 0.4654$) (see Table 2).

Table 2. Awareness of young adults by age

Evaluation Metric	Under '20 Years Old (n = 104)	20 Years Old and Older (n = 52)	p-value

Satisfactory (3)	14 (34%)	33 (29%)	
Knowledgeable (4-5)	19 (46%)	73 (65%)	

Males vs Females

Males and females reported self-knowledge in equivalent proportions; 41% of males and females alike felt that they were knowledgeable about the disease ($p = 0.9343$). 66% of males and 83% of females correctly identified that Alzheimer's disease is a subtype of dementia. While not statistically significant, there is a strong trend to suggest that females are more knowledgeable than their male counterparts for this evaluation metric ($p = 0.0556$). There does not appear to be any differences between the sexes for identifying if Alzheimer's disease is normal with respect to the aging process, with 80% of males and 84% of females correctly answering false ($p = 0.7699$). The vast majority of males (90%) and females (92%) were aware that Alzheimer's disease worsens over time ($p = 0.6186$). Females are more aware than males that Alzheimer's disease is not curable ($p = 0.0065$).

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 61)	Not Affected (n = 95)	p-value
Self-belief of being knowledgeable			0.2163
Yes	30 (49%)	33 (35%)	
Neutral	24 (39%)	48 (51%)	
No	7 (11%)	14 (15%)	
Alzheimer's is a subtype of dementia			0.2483
True	48 (79%)	75 (79%)	
False	7 (11%)	5 (5%)	
Not Sure	6 (10%)	15 (16%)	
Alzheimer's is normal with respect to aging			0.7266
True	6 (10%)	9 (9%)	
False	49 (80%)	80 (84%)	
Not Sure	6 (10%)	6 (6%)	
Alzheimer's worsens over time			0.3591
True	58 (95%)	84 (88%)	
False	0 (0%)	3 (3%)	
Not Sure	3 (5%)	8 (8%)	
No cure to Alzheimer's			0.0473
True	57 (93%)	81 (85%)	
False	1 (2%)	0 (0%)	
Not Sure	3 (5%)	14 (16%)	
Alzheimer's is leading cause of death			0.0765
True	17 (28%)	17 (18%)	
False	16 (26%)	41 (43%)	
Not Sure	28 (46%)	37 (39%)	
Overall Score			0.4761
Poor (1-2)	4 (7%)	12 (13%)	
Satisfactory (3)	20 (33%)	27 (28%)	
Knowledgeable (4-5)	37 (61%)	56 (59%)	

While 93% of females correctly identified that there is no cure for Alzheimer's, only 76% of males answered similarly. There is also a trend to suggest differences exist between sexes in terms of identifying Alzheimer's as a leading cause of death ($p = 0.1058$). While males and females both correctly identified the high mortality associated with the disease only around 20% of the time, females (47%) were much more likely than males (29%) to admit that they were not sure about the answer to this evaluation metric. Overall, it appears that statistically significant sex differences in terms of Alzheimer's awareness do exist, with females generally

being more knowledgeable than males ($p = 0.0308$). While 65% of females were well-informed about Alzheimer's disease, only 46% of males were classified as being knowledgeable; 20% of males were fairly unaware of the disease and its implications, while only 7% of females had overall poor awareness.

Affected vs Not Affected

This study indicated that 39% of young adults in Toronto know at least one relative who has been affected directly by Alzheimer's disease (affected subgroup). It does not appear that individuals in this affected group believe that they are more knowledgeable about the disease than individuals who have not had a family member affected by the disease (unaffected/not affected subgroup); 49% of participants in the affected subgroup and 35% of participants in the not affected subgroup believe that they are well-informed about the disease ($p = 0.2163$). 79% of participants in both subgroups correctly identified that Alzheimer's is a subtype of dementia ($p = 0.2483$). Both subgroups are equally educated with respect to their awareness that Alzheimer's is not normal with respect to the aging process ($p = 0.7266$), and that Alzheimer's worsens over time ($p = 0.3591$). A difference was noted between the two groups with respect to their knowledge of whether Alzheimer's disease has a cure. It appears that participants who have an affected family member were more aware that Alzheimer's is incurable (93%) than the subgroup consisting of individuals who have not had an affected family member (85%) ($p = 0.0473$). While statistically insignificant, there is a strong trend to suggest that individuals in the affected subgroup are more aware than their not affected subgroup counterparts with regards to if Alzheimer's is a leading cause of death ($p = 0.0765$). 28% of individuals in the affected cohort correctly identified that Alzheimer's disease is a major cause of death, while only 18% of participants in the not affected subgroup correctly answered this question; however, relative awareness of the mortality of Alzheimer's disease is disturbingly low across both subgroups. There was no difference noted in terms of overall awareness scores ($p = 0.4761$); 61% and 59% of individuals in the affected and not affected cohorts, respectively, were generally well informed about Alzheimer's disease and its implications (see Table 4).

DISCUSSION

It is interesting that while only 40% of individuals believed they were well-informed about Alzheimer's, 60% of participants in this study were actually determined to be knowledgeable about the disease. However, overall awareness scores for individuals in Toronto, Canada appear to be significantly lower than those reported by Chow et al. where 75% to 80% of young adults were knowledgeable about the disease [8, 10]. This may be the result of the larger sample size of this study, but also slight sociocultural differences between the two populations may result in different levels of disease awareness in London, Kingston and Toronto. However, in both studies, overall Alzheimer's awareness is quite high. This high awareness among young adults might translate to earlier detection of the disease, and

ultimately earlier treatment and better prognosis, when this cohort approaches older ages at which Alzheimer's tends to develop.

It is interesting that no significant differences exist in terms of awareness levels between participants with a relative affected by Alzheimer's and those with unaffected relatives. However, it is encouraging that while approximately 39% of the young adult population knows of at least one family member who is or was affected by the disease, overall Alzheimer's awareness levels among young adults remain significantly higher than this proportion. This will hopefully translate to a continued high level of awareness of the disease and its implications in years to come.

This study validates the finding by Chow et al. [8] that young women are more knowledgeable than young men about Alzheimer's disease. This might be as a result of sex-role stereotypes in Canadian culture where young women are more likely to have an invested interest in their own well-being than that of young men. This may give rise to young women becoming more informed about prevalent diseases such as Alzheimer's disease. However, it is also quite possible that many of the young women in this particular cohort were particularly interested in educating themselves about Alzheimer's disease, or that the young men in this sample were generally uninterested in learning about the disease, or both. Further research should investigate if this pattern of better disease understanding by females is generalizable to other pathological conditions, and what the underlying reasons are for these differences.

Perhaps the most concerning finding of this study was the shockingly high proportion of young adults who were unaware of Alzheimer's lethal prognosis. Overall, only 22% of individuals were aware that Alzheimer's disease-related complications are a leading cause of death. This is alarming, especially considering that the Alzheimer's Association reports that Alzheimer's disease is the sixth leading cause of death in the United States, which means that it kills at a rate higher than breast cancer and prostate cancer combined [11]. It is possible that the unfortunate stigmatization of mental illnesses in contemporary society makes it difficult for individuals to draw a connection between a psychological disorder and negative physical outcomes. Programs centred around Alzheimer's disease awareness should consider placing greater emphasis on the high mortality rate associated with this psychopathological condition.

This study was not without limitations. The quiz consisted of an online survey, so there exists the possibility that participants could have employed reference resources to assist their answers. This is unavoidable due to the survey's medium, but was hopefully minimized by assuring participants that the quiz was merely an assessment of awareness and should be answered honestly and individually.

In conclusion, 60% of young adults in Toronto are generally well aware about Alzheimer's disease and its implications, while only 10% were poorly informed. No differences in awareness were noted between individuals aged under 20 years old or aged 20 years old or older. Up to 39% of participants knew at least one family member who has been affected directly by Alzheimer's disease, but no significant differences existed between their levels of awareness and awareness levels of individuals with no familial connections to the disease. It is interesting that females were significantly more aware than males regarding Alzheimer's disease; future research should aim to investigate the underlying reasons for these sex differences. It is concerning that only slightly more than 20% of young adults correctly identified that Alzheimer's is a leading cause of death; it may be worthwhile for future awareness campaigns to emphasize the high mortality rate associated with Alzheimer's

disease. Overall, much like the results reported by Chow et al. [8], this study is promising in that it suggests that young adults are relatively well-aware of Alzheimer's disease.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

Prior studies have been conducted to determine the awareness levels of young adults in London, Kingston and Toronto. While these studies have shown that young adults seem to be well-aware of the illness, there still exists variation between study locations in the proportion of individuals who have a family member affected, as well as the perceived and actual knowledge about the disease. The aim of this study was to investigate into the awareness of Alzheimer's disease among young adults in Ottawa, Canada. A survey, the same as those previously employed by other studies, was designed to evaluate the awareness of young adults in Ottawa, Ontario, Canada. Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). A total of 13 people consented and completed the study. 85% of young adults in Ottawa, Canada are aware of Alzheimer's disease, although only 69% believed that they are knowledgeable. Given that 46% of young adults have a family member affected by the illness it seems that young adults are adequately aware such that they can understand the disease their family members are affected from. Future studies should look into repeating this study with a large sample size to determine if there is any difference in responses between subgroups.

INTRODUCTION

Dementia is ever-present in our population [1], and coupled with comorbidities can often result in poor quality of life and quality of care [2]. Although tools have been developed for healthcare professionals to help care for these patients [3], there is additional onus on the family members to improve quality of care by educating themselves about the illness.

Prior studies have been conducted to determine the awareness levels of young adults in London [4], Kingston [5] and Toronto [6]. The original study conducted in London, Canada, determined that only 48% of the population believed that they were knowledgeable about the illness, but 75% were well-aware of the disease [4]. The survey determined that only 31% of young adults have a family member affected by Alzheimer's disease - a much larger proportion believed they were knowledgeable, and an even greater percentage were aware of the illness [4].

The studies by Chow et al. in Kingston [5] and Borean et al. in Toronto [6] confirmed these trends. 38% of individuals in Kingston have a family member affected by Alzheimer's disease, while 58% and 80%, respectively, believed they were knowledgeable and actually were knowledgeable [5]. In Toronto, 39% had familial ties to Alzheimer's disease, 40% believed that they were knowledgeable, and 60% completed the assessment such that they determined to be knowledgeable [6].

While these studies have shown that young adults seem to be well-aware of the illness, there still exists variation between study locations in the proportion of individuals who have a family member affected, and also the perceived and actual knowledge about the disease. The aim of this study was to investigate the awareness of Alzheimer's disease among young adults in Ottawa, Canada.

SURVEY METHOD

A survey, the same as that used by Chow et al. in London [4], was designed to evaluate the awareness of young adults in Ottawa, Ontario, Canada, see chapter 2 [7]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [7]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [7]; only those who recorded Ottawa, Canada as their place of residence were included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [7]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [7].

The main objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). Other objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The six items - 1 reflection and 5 knowledge questions - on page 3 were presented using descriptive statistics. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's, only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

WHAT WE FOUND

A total of 13 people consented and completed the study. Over half (69%) believed they were knowledgeable about Alzheimer's disease, 23% reserved judgement, 8% admitted that they were not knowledgeable about Alzheimer's disease. 77% of participants correctly answered that Alzheimer's is a subtype of dementia, with 23% incorrectly responding false. Only 2 people (15%) answered incorrectly or admitted a knowledge deficit with respect to Alzheimer's disease and the aging process. All 13 participants correctly answered that Alzheimer's worsens over time, and correctly recognized that there is no cure to Alzheimer's disease. 39% incorrectly believed that Alzheimer's disease is not a leading cause of death, with only 23% of responders correctly answering the question. 85% of young adults scored 4 or 5 out of 5, while 1% scored 3 out of 5 and 1% received a score between 0 and 2 out of 5 (see Table 1).

Under 20 Years Old vs 20 Years Old and above

Of the 13 participants, 7 were under the age of 20 years old and 6 were 20 years of age and older. 71% of those under 20 years old believed that they were knowledgeable, while 67% of those 20 years and older had a similar belief ($p = 0.9999$). 57% and 100% of the two groups, respectively, correctly believed that Alzheimer's is a subtype of dementia ($p = 0.3147$). There was no difference between the two groups with respect to the question about Alzheimer's disease and normal aging ($p = 0.9999$); 14% of those under 20 years old and 17% of those 20 years and older correctly responded that Alzheimer's is not part of the normal aging process. All young adults, regardless of age, correctly believe that Alzheimer's worsens over time as well as correctly identified that there is no cure for Alzheimer's ($p =$

0.9999). Both groups seemed to be equally-unsure about whether Alzheimer's is a leading cause of death ($p = 0.2424$), with only 57% and 17% of those under 20 and over 20, respectively, correctly answering the question. 14% of the individuals under 20, respectively, had a satisfactory score, whereas 71% and 100% of the same two groups were knowledgeable according to the five-point score ($p = 0.8283$) (see Table 2).

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 13)
Self-belief of being knowledgeable	
Yes	9 (69%)
Neutral	3 (23%)
No	1 (8%)
Alzheimer's is a subtype of dementia	
True	10 (77%)
False	1 (23%)
Not Sure	2 (15%)
Alzheimer's is normal with respect to aging	
True	2 (15%)
False	11 (85%)
Not Sure	0 (0%)
Alzheimer's worsens over time	
True	13 (100%)
False	0 (0%)
Not Sure	0 (0%)
No cure to Alzheimer's	
True	13 (100%)
False	0 (0%)
Not Sure	0 (0%)
Alzheimer's is leading cause of death	
True	5 (39%)
False	5 (39%)
Not Sure	3 (23%)
Overall Score	
Poor (1-2)	1 (8%)
Satisfactory (3)	1 (8%)
Knowledgeable (4-5)	11 (85%)

Table 2. Awareness of young adults by age

Evaluation Metric	Under 20 Years Old (n = 7)	20 Years Old and Older (n = 6)	p-value
Self-belief of being knowledgeable			0.9999
Yes	5 (71%)	4 (67%)	
Neutral	1 (14%)	2 (33%)	
No	1 (14%)	0 (0%)	
Alzheimer's is a subtype of dementia			0.3147
True	4 (57%)	6 (100%)	
False	1 (14%)	0 (0%)	
Not Sure	2 (29%)	0 (0%)	
Alzheimer's is normal with respect to aging			0.9999
True	1 (14%)	1 (17%)	
False	6 (86%)	5 (83%)	
Not Sure	0 (0%)	0 (0%)	

Evaluation Metric	Under 20 Years Old (n = 7)	20 Years Old and Older (n = 6)	p-value
Alzheimer's worsens over time			0.9999
True			
False	7 (100%)	6 (100%)	
Not Sure	0 (0%)	0 (0%)	
	0 (0%)	0 (0%)	
No cure to Alzheimer's			0.9999
True	7 (100%)	6 (100%)	
False	0 (0%)	0 (0%)	
Not Sure	0 (0%)	0 (0%)	
Alzheimer's is leading cause of death			0.2424
True	4 (57%)	1 (17%)	
False	1 (14%)	4 (67%)	
Not Sure	2 (29%)	1 (17%)	
Overall Score			0.9999
Poor (1-2)	1 (14%)	0 (0%)	
Satisfactory (3)	1 (14%)	0 (0%)	
Knowledgeable (4-5)	5 (71%)	6 (100%)	

Males vs Females

1 responder did not identify as male or female; 4 identified as male and 8 identified as female. There was no difference with respect to self-belief between the two genders ($p = 0.4909$), with 50% of males and 75% of females believing that they are knowledgeable. Females and males were equally knowledgeable that Alzheimer's disease is a subtype of dementia, with 75% of each sex answering correctly ($p = 0.9999$). 50% of males and 100% of females correctly answered that Alzheimer's is not normal with respect to aging ($p = 0.0909$). All participants of both groups responded that Alzheimer's does indeed worsen over time and that there is indeed no cure to Alzheimer's ($p = 0.9999$). While 50% of females responded that they were unsure about whether Alzheimer's is a leading cause of death, only 25% of males similarly responded so ($p = 0.7576$). 75% of males and 88% of females received a score that led to an inference of them being knowledgeable about the disease ($p = 0.5758$) (see Table 3).

Affected vs Not Affected

Of the 13 participants, 7 do not have a family member affected by Alzheimer's disease, to their knowledge. Of those affected and not affected by Alzheimer's disease, 83% and 71% respectively correctly acknowledged that Alzheimer's is a subtype of dementia ($p = 0.9999$). 17% and 14% respectively correctly responded that Alzheimer's is not normal with respect to aging ($p = 0.9999$). All participants answered that Alzheimer's worsens over time and correctly identified that there is no cure to Alzheimer's disease ($p = 0.9999$). Those affected by Alzheimer's disease more frequently responded that Alzheimer's is not a leading cause of death (33% vs 43%) as opposed to simply admitting they were unsure (17% vs 29%) ($p = 0.9999$). 14% of those not affected had a satisfactory score of 3 out of 5, while 83% and 86% respectively scored 4 or 5 out of 5 ($p = 0.9999$) (see Table 4).

Table 3. Awareness of young adults by sex

Evaluation Metric	Male (n = 4)	Female (n = 8)	p-value
Self-belief of being knowledgeable			0.4909
Yes	2 (50%)	6 (75%)	
Neutral	1 (25%)	2 (25%)	
No	1 (25%)	0 (0%)	
Alzheimer's is a subtype of dementia			0.9999
True	3 (75%)	6 (75%)	
False	0 (0%)	1 (12%)	
Not Sure	1 (25%)	1 (12%)	
Alzheimer's is normal with respect to aging			0.0909
True	2 (50%)	8 (100%)	
False	2 (50%)	0 (0%)	
Not Sure	0 (0%)	0 (0%)	
Alzheimer's worsens over time			0.9999
True			
False	4 (100%)	8 (100%)	
Not Sure	0 (0%)	0 (0%)	
No cure to Alzheimer's			0.9999
True	4 (100%)	8 (100%)	
False	0 (0%)	0 (0%)	
Not Sure	0 (0%)	0 (0%)	
Alzheimer's is leading cause of death			0.7576
True	1 (25%)	4 (50%)	
False	2 (50%)	2 (25%)	
Not Sure	1 (25%)	2 (25%)	
Overall Score			0.5758
Poor (1-2)	1 (25%)	0 (0%)	
Satisfactory (3)	0 (0%)	1 (12%)	
Knowledgeable (4-5)	3 (75%)	7 (88%)	

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 6)	Not Affected (n = 7)	p-value
Self-belief of being knowledgeable			0.3392
Yes	3 (50%)	6 (86%)	
Neutral	2 (33%)	1 (14%)	
No	1 (17%)	0 (0%)	
Alzheimer's is a subtype of dementia			0.9999
True	5 (83%)	5 (71%)	
False	0 (0%)	1 (14%)	
Not Sure	1 (17%)	1 (14%)	
Alzheimer's is normal with respect to aging			0.9999
True	1 (17%)	1 (14%)	
False	5 (83%)	6 (86%)	
Not Sure	0 (0%)	0 (0%)	
Alzheimer's worsens over time			0.9999
True			
False	6 (100%)	7 (100%)	
Not Sure	0 (0%)	0 (0%)	

Evaluation Metric	Affected (n = 6)	Not Affected (n = 7)	p-value
No cure to Alzheimer's			0.9999
True	6 (100%)	7 (100%)	
False	0 (0%)	0 (0%)	
Not Sure	0 (0%)	0 (0%)	
Alzheimer's is leading cause of death			0.9999
True	2 (33%)	3 (43%)	
False	3 (50%)	2 (29%)	
Not Sure	1 (17%)	2 (29%)	
Overall Score			0.9999
Poor (1-2)	1 (17%)	0 (0%)	
Satisfactory (3)	0 (0%)	1 (14%)	
Knowledgeable (4-5)	5 (83%)	6 (86%)	

DISCUSSION

This study validated those results revealed in prior studies [4-6]. In this population, 69% of respondents believed that they are well-aware of the illness, when it turned out that 85% were adequately aware. Both of these ratios are noticeably higher than the percentage of young adults who have a family member affected by Alzheimer's (46%). In line with other studies, the results suggest that young adults are more aware of the illness than they perceive themselves to be.

Between the three studies that previously looked into Alzheimer's awareness, two studies reported a statistically significant difference in awareness between sexes [4, 6], while one study found no difference [5]. The results of this study support the study by Chow et al. [5] conducted in Kingston, Canada, that there is no difference between males and females in terms of disease awareness. However, it is important to note that the sample size of this study and that by Chow et al. in Kingston [5] are substantially smaller than the other two studies [4, 6]; there is hence lower statistical power and it would be more difficult to detect a significant difference.

This study has its limitations. The sample size of this study was substantially smaller than prior studies and hence could have decreased statistical power when detecting for differences. A large sample size could have been accrued should the study have been designed without the need to enter an email address, based on the researchers' personal interactions with the population and based on past experience. Also, there exists the possibility of cheating when completing the quiz portion of the survey, which would lead to an artificially higher proportion of individuals who would be knowledgeable.

In conclusion, 85% of young adults in Ottawa, Canada, are aware of Alzheimer's disease, although only 69% believed that they are knowledgeable. Given that 46% of young adults have a family member affected by the illness, it seems that young adults are adequately aware of the disease that their family members are affected by. Future studies should look into repeating this study with a large sample size to determine if there is any difference in responses between subgroups.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

Alzheimer's disease is a subtype of dementia, which substantially impairs quality of life. A study conducted in the United States of America reports that 10.3% of those aged 65 and older were diagnosed with Alzheimer's disease. Many cases of Alzheimer's are not detected until the later stages, however this could be prevented by increasing the awareness of disease. The aim of this study was to investigate the awareness level of young adults in Hamilton, Canada. A survey was designed and circulated with the primary objective to identify how aware young adults were regarding Alzheimer's disease, regardless of age, sex and family history of the disease. The secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease. This survey was completed by 67 participants, of which 34% believed they were knowledgeable about the disease while only 19% actually were; this study yielded the opposite trend from the previously conducted studies, which all supported a trend that more adolescents were knowledgeable about the disease than they believed. Steps should be taken to increase the awareness among young adults in this city.

* Corresponding Author's Email: rchow48@uwo.ca.

INTRODUCTION

Alzheimer's Disease is a very prevalent condition and a subtype of dementia that reduces the quality of life of many seniors [1]. According to a study conducted in the United States of America, an alarming 10.3% of those aged 65 and older were diagnosed with Alzheimer's disease [2]. This rate is especially concerning due to the multiple health conditions that have been proven follow the disease, including depression [3].

Many cases of Alzheimer's are not detected until the later stages of the condition. This could be prevented by increasing the awareness of the conditions in the general public. In order to assess the current knowledge level about Alzheimer's Disease, a study was conducted in several cities in Ontario, including London, Toronto, Kingston and Ottawa [4-7]. The original study conducted in London stated that 31% of respondents had a family member who was affected by Alzheimer's, yet 48% of those who answered believed they were knowledgeable about the disease [3]. Astonishingly, the results yielded 75% were actually quite knowledgeable about the condition, which suggests that having a family member affected by the condition does not correlated with the general knowledge in the population [3]. The subsequent studies conducted in Kingston, Toronto and Ottawa also support the trends that were unearthed in the London study [3-7]. In order to verify this trend and further assess the general knowledge regarding Alzheimer's disease, this study was conducted in Hamilton, Ontario, Canada.

OUR STUDY

A survey was created to evaluate how knowledgeable young adults in Hamilton, Ontario, Canada were about Alzheimer's disease, see chapter 2 [8]. On the first page, there was a consent form where participants could fill in their email and have a copy of the form sent to them [8]. Those who consented to the survey were redirectly to complete three demographics-related questions which inquired about the respondent's primary place of residence, age and sex [8]; only those who recorded Hamilton, Canada, as their place of residence were included in this study. The next page included a reflection question, followed by 5 knowledge-based questions regarding Alzheimer's disease [8]. Finally, the last page of the survey inquired about the participant's familial incidences of Alzheimer's disease and, if applicable, how often they visited an affected member [8].

This survey was designed to identify how aware young adults were regarding Alzheimer's disease, regardless of age, sex and family history of the disease. The secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. The correct answers for the knowledge based questions are as follows:

Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Those with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; participants with 3 were marked as having satisfactory knowledge; respondents scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based on the ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). In order to determine whether there was a significant difference in the awareness among these groups, Fisher-exact tests were conducted. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

FINDINGS

This survey was completed by 67 consenting participants. Of this population, 34% believed that they were knowledgeable about the condition, 13% said they had low knowledge of the subject and 52% were undecided. 73% of respondents correctly stated that Alzheimer's is a subtype of dementia, 12% reported it as false and 15% were unsure. The majority of respondents, 88%, correctly commented that Alzheimer's Disease is not normal with respect to aging, 4% said it was and 9% were unsure. 93% of the participants agreed that Alzheimer's worsens over time while 2% denied this and 6% were unsure. In terms of treating the disease, 96% correctly identified that there was no cure while 4% were unsure. 25% of respondents stated that Alzheimer's is a leading cause of death, 33% said it wasn't while 42% were unsure. Overall, 25% of participants lacked knowledge about the disease, 55% had a satisfactory level and 19% were very knowledgeable about the condition (see Table 1).

Under 20 Years Old vs 20 Years Old and above

There was statistically no difference between the two groups in terms of their self belief of the knowledge regarding the disease. 37% of those under 20 years old and 29% of those older than 20 years old ($p = 0.7765$) thought they were knowledgeable. Among those under age 20, 67% and 83% of those older than 20 believed that Alzheimer's is a subtype of dementia ($p = 0.3204$). 88% of both groups identified that Alzheimer's is normal with respect to aging ($p = 0.9999$). 93% of those under 20 years old and 92% of those older than 20 agreed that Alzheimer's worsens over time ($p = 0.7547$). Of those under 20, 98% and 92% of over 20 stated that there was no cure to cancer ($p = 0.2900$). 40% of those under age 20 and 21% of those older than 20 years old commented that Alzheimer's is not a leading cause of death ($p = 0.3363$). To sum, 58% and 50% of those 20 years old and younger and those older than 20 respectively had satisfactory knowledge about the disease ($p = 0.3303$) (see Table 2).

Knowledgeable (4-5)	6 (14%)	7 (29%)	

Males vs Females

36% and 34% of males and females respectively believed they were knowledgeable about Alzheimer's disease ($p = 0.9999$). 64% and 75% of males and females respectively stated that Alzheimer's is a subtype of dementia ($p = 0.6475$). 82% of males and 89% of females said that Alzheimer's was not a normal aging process ($p = 0.4889$). 91% of males and 93% of females identified that Alzheimer's worsens over time ($p = 0.6045$). All of the male respondents and 95% of the females correctly identified that there is no cure to the disease ($p = 0.9999$). 18% and 27% of males and females respectively said that Alzheimer's is the leading cause of disease ($p = 0.6448$). Overall, 55% of both cohorts had a satisfactory level of knowledge regarding the disease ($p = 0.5489$) (see Table 3).

Table 3. Awareness of young adults by sex

Evaluation Metric	Male (n = 11)	Female (n = 56)	p-value
Self-belief of being knowledgeable			0.9999
Yes	4 (36%)	19 (34%)	
Neutral	6 (55%)	29 (52%)	
No	1 (9%)	8 (14%)	
Alzheimer's is a subtype of dementia			0.6475

Satisfactory (3)	6 (55%)	31 (55%)	
Knowledgeable (4-5)	1 (9%)	12 (21%)	

Affected vs Not Affected

50% of those with an affected family member and 29% of those who have never had an affected family member believed that they were knowledgeable about Alzheimer's ($p = 0.0694$). 72% of those affected and 73% of those who were not affected knew that Alzheimer's is a subtype of dementia ($p = 0.9999$). All of the participants who had a family member who was diagnosed with Alzheimer's identified that the disease was not normal with respect to aging, along with 84% of the other cohort ($p = 0.2929$). 100% of those affected and 90% of those who weren't were able to identify that Alzheimer's worsens over time ($p = 0.6841$). Of those affected and 94% of those who were not reported that there was no cure to Alzheimer's ($p = 0.5581$). 22% of those affected and 27% of those who weren't said that Alzheimer's was the leading cause of death ($p = 0.5010$). Overall, 61% of those affected and 53% of those who weren't answered 3 of the 5 questions correctly ($p = 0.8709$) (see table 4).

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 18)	Not Affected (n = 49)	p-value
Self-belief of being knowledgeable			0.0694

Knowledgeable (4-5)	3 (17%)	10 (20%)	

DISCUSSION

The results of this survey are different than the trend reported by the studies conducted in London, Toronto, Kingston and Ottawa [4-7]. 34% of respondents believed they were knowledgeable about Alzheimer's disease, however only 19% scored above a 4 on the

questionnaire. This result is disappointing, as participants are confident about their knowledge, however they are not very aware of the disease. A higher awareness would result in better future caregivers as these adolescents mature into adults, thus it is necessary to increase the awareness in this population.

The subgroup analyses further emphasizes this unique trend found in Hamilton, Canada. For those aged 20 and older, there were an equal number of participants who achieved a score of 4 or higher on the questionnaire as the number of individuals who believed they were knowledgeable. However, for the younger age cohort, there were less participants who were actually knowledgeable than those who believed they were. This trend continues when looking at the different sexes; both males and females thought they were more knowledgeable about the disease than they actually were. Those who had a family member affected by the disease were just as unaware about their metacomprehension as those who weren't as this categorization fell inline with the trend found in other subgroup analyses as well.

This survey also reports that 27% of participants had a family member who was affected by Alzheimer's disease, which is a lower rate stated by the studies conducted done in London (31%), Kingston (38%), Ottawa (46%) and Toronto (39%) [4-7].

There were a few limitations for this study. There was a small sample size, which led to a the detection of trends rather than significant differences, this issue could have been overcome with a larger sample size. A large sample size could perhaps been accrued should the study have been designed without the need to enter an email address, based on the researcher's personal interactions with the population and based on past experience [9-11]. Participants could have used external sources to help them with the answers; this limitation is hard to overcome as the survey was completed online. The respondents were informed that the survey was being done to assess their knowledge and thus should be answered honestly.

To conclude, 27% of respondents had a family member who was affected by Alzheimer's disease. While 34% of participants believed they were knowledgeable about the disease, this study shows that in reality only 19% were truly aware. This study yielded the opposite trend from the previously conducted studies, which all supported a trend that more adolescents were knowledgeable about the disease than they believed [4-7]. There should be some action taken to increase the awareness of this disease among the young adults in Hamilton, Canada. Increasing the knowledge of this population will have a plethora of benefits, as they will soon be the caregivers and health providers. In order to investigate whether the general awareness has gone up in the population, further studies should be conducted in Hamilton in the future.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

Chapter 233

AWARENESS OF ALZHEIMER'S DISEASE AMONG YOUNG ADULTS IN WATERLOO, CANADA

ABSTRACT

Family members of patients suffering from Alzheimer's disease may help healthcare professionals improve standard of care and hence quality of life by being knowledgeable about the disease. The purpose of this investigation was to study the awareness level of young adults in Waterloo with respect to Alzheimer's disease. 100 young adults in Waterloo consented and completed a survey, and 41 of the 100 had a family member affected by Alzheimer's disease. Of the 100, 65% of the population were knowledgeable about the disease, although only 41% believed they were well-aware. This trend is very similar to those previously reported in Ontario.

INTRODUCTION

Family members of patients suffering from Alzheimer's disease may help healthcare professionals improve standard of care and hence quality of life by being knowledgeable about the disease [1].

A prior study [2] conducted in London, Canada examined the awareness of the young adults in that area. It discovered that 75% of the young adults were knowledgeable about the disease, but a much smaller number thought they were well informed (48%). 31% of the same

* Corresponding Author's Email: rchow48@uwo.ca.

group had a family member affected by Alzheimer's disease, and overall it appeared that young adults are generally quite knowledgeable in this area.

Several similar studies were conducted in order to confirm these conclusions in various areas [3-9]. In Ontario (the same province as Waterloo) three studies were conducted [3-5]. In Kingston, 60% of the population was knowledgeable, compared to the 58% that believed they were and the 38% who had a family member affected by the disease [3]. In Toronto, Borean et al. [4] also confirmed the trend, as 39% of the cohort had a family member with the disease, 40% believed they were knowledgeable and 60% actually were well-aware of the disease. In Ottawa, the same trend was found in young adult populations as 46% of the group had family members affected, 69% believed they were knowledgeable, and 85% were knowledgeable according to the assessment tool [5]. Finally, in Hamilton, the trend was contradicted as 34% of the cohort believed they were well-aware, yet only 19% were in reality. There was also a lower amount of people affected, as only 27% of participants were indirectly affected by the disease through family.

The aim of this study was to further pursue whether this trend holds true in another location in Ontario, Canada (Waterloo) using a more substantial sample size ($n = 100$).

OUR SURVEY

A questionnaire was made to evaluate the awareness of young adults in Waterloo, Canada, see chapter 2 [10]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [10]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [10]; only those who recorded Waterloo as their place of residence were included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [10]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their affected relative [10].

The main objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). Other objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The same statistical analysis was conducted by Chow et al. in the initial survey in London, Canada. Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only

treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 100)
Self-belief of being knowledgeable	
Yes	41 (41%)
Neutral	50 (50%)
No	9 (9%)
Alzheimer's is a subtype of dementia	
True	73 (73%)
False	8 (8%)
Not Sure	19 (19%)
Alzheimer's is normal with respect to aging	
True	11 (11%)
False	84 (84%)
Not Sure	5 (5%)
Alzheimer's worsens over time	
True	90 (90%)
False	5 (5%)
Not Sure	5 (5%)
No cure to Alzheimer's	
True	90 (90%)
False	3 (3%)
Not Sure	7 (7%)
Alzheimer's is leading cause of death	
True	16 (16%)
False	48 (48%)
Not Sure	36 (36%)
Overall Score	
Poor (0-2)	14 (14%)
Satisfactory (3)	21 (21%)
Knowledgeable (4-5)	65 (65%)

Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

OUR FINDINGS

In total, 100 young adults consented and completed the provided survey within the region of Waterloo. 50% of the group gave a neutral response pertaining to their believed awareness level of the disease. 41% of the cohort believed they had a high level while only 9% thought they had a low level of knowledge. Most of the participants (73%) correctly answered that

Alzheimer's is a subtype of dementia, 84% correctly responded that Alzheimer's is not normal with respect to the aging process, 90% said correctly that Alzheimer's worsens over time, and 90% detailed that there is no cure to Alzheimer's. On the contrary, only 16% of respondents correctly noted that Alzheimer's is a leading cause of death. Altogether 65% of participants were very knowledgeable, while 21% had satisfactory knowledge and 14% had little knowledge about the disease (see Table 1).

Under 20 Years Old vs 20 Years Old and above

39 of the 100 participants were under 20 years old, while 61 were 20 years old and older. There were no differences between the two age groups in any of the responses. 48% of those 20 years old and older refused to comment about their level of awareness, and similarly 54% of those under 20 years of age answered neutrally ($p = 0.5955$). Also, 77% and 70% of the younger and older group, respectively, recognized that Alzheimer's is a subtype of dementia ($p = 0.4465$). Thirdly, 85% and 84% of the two populations, respectively, chose that Alzheimer's is not part of the normal aging process ($p = 0.1064$). 95% of the younger group and 87% of the over 20 group correctly verified that Alzheimer's worsens over time ($p = 0.5254$). 95% of the younger cohort and 87% of the older cohort recognized that there is no cure for Alzheimer's ($p = 0.4359$). Unlike many of the other studies, most of the respondents recognized that Alzheimer's is a leading cause of death, with only 49% and 48% believing it is not ($p = 0.8553$). Altogether, 64% and 66% of the younger and older cohort, respectively, were deemed knowledgeable ($p = 0.1942$) (see Table 2).

Males vs Females

Of the 100, there were 30 male subjects and 69 female subjects, while one participant preferred not to answer. 53% of males and 48% of females remained neutral about they were knowledgeable about Alzheimer's disease ($p = 0.8056$). 78% of females and 63% of males, correctly stated that Alzheimer's is a subtype of dementia ($p = 0.0348$). Secondly, 90% of women responded that Alzheimer's is not part of the normal aging process while only 70% of males gave the correct response ($p = 0.0147$). Also, 94% of females correctly identified that Alzheimer's worsens over time, compared to only 80% for males ($p = 0.0359$). Fourthly, 93% of females chose that there is no cure to Alzheimer's compared to 83% of males ($p = 0.3561$). Finally, only 20% of women correctly recognized that Alzheimer's is a leading cause of death whereas only 7% for males made this correct selection ($p = 0.1734$). The data shows that females are clearly more knowledgeable than males about Alzheimer's disease, with 71% appearing to be well-aware, compared to only 53% of males ($p = 0.1439$) (see Table 3).

Affected vs Not Affected

41% of the 100 had family members who were affected by Alzheimer's disease, whereas 59% did not have a family member to their knowledge afflicted by the disease. Firstly, 27% of those not affected and 61% of those affected deemed themselves to be knowledgeable about the disease ($p = 0.0018$). Also, 76% and 71% of those affected and unaffected, respectively, correctly identified that it is a subtype of dementia ($p = 0.6207$). 89% and 81% of the same groups, noted that Alzheimer's is not normal with respect to aging ($p = 0.7076$). Meanwhile, 88% of those unaffected noted that Alzheimer's worsens over time and 93% for those affected gave the same answer ($p = 0.8745$). 92% of the unaffected correctly chose that there is no cure to Alzheimer's, compared to 88% of the affected ($p = 0.5791$). Finally, only 10% of those affected and an underwhelming 20% of those unaffected correctly thought that Alzheimer's is a leading cause of death ($p = 0.2760$), following the low percentage trend in this category. Overall, 68% of those affected and 62% of those unaffected had excellent knowledge about the disease ($p = 0.7255$) (see Table 4).

Table 2. Awareness of young adults by age

DISCUSSION

This study followed the exact trend of the various other studies done in Ontario, as a large majority of the young adults were quite knowledgeable about the disease (65%), while many less had family affected by it (41%), and only 41% of participants initially believed that they would be knowledgeable. Interesting results are yielded from the gender-split results, as well as the results from the affected vs. non-affected portion. In the gender split, there was three instances of significant differences between male and female responses ($p\text{-value} < 0.05$) showing that for three of the quiz questions, females statistically gave the correct response much more than males, and overall were 18% more knowledgeable (71% vs 53%). This difference could be caused by more females conducting prior research about the disease, more females cheating during the quiz, or even more females taking the quiz more seriously. In the affected vs unaffected split, in all the questions, the affected are more knowledgeable (most likely resulting from additional research), except the last one, "Is Alzheimer's a leading cause of death?". This variation could possibly exist because although they might have a family member with the illness, the family member may not have passed away, causing them to believe it is not a big factor in death. Also, Alzheimer's does not directly cause the death of someone, so it is possible that in their research they discovered this and answered the question believing that because it is not a direct killer, it does not lead to death.

This study was not without limitations. Although this study did have a much larger sample size than the other studies in the series [3-9], 100 participants is still not as large as it could be. Also, while filling out the quiz portion of the survey, it is possible that participants could have used online resources or other assistance to cheat, thus skewing the amount of knowledgeable subjects.

In conclusion, the trend noted by other studies [3-9] was confirmed in Waterloo, Canada, as 65% of participants were knowledgeable whereas only 41% believed they were, while only 41% were affected by the disease. Further studies should attempt to identify the difference in male and female awareness level in the Waterloo area, investigate the reason of why the amount of correct responses to the last question were comparatively low, as well as try to identify if the same overall trend continues in more areas around the globe.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

Infinitas Research Group, London, Ontario, Canada

ABSTRACT

There have been studies that revealed a trend that young adults are adequately aware of the disease. However, there exists variation between the studies in the proportion of individuals who have a family member affected, who believed they are aware, and who are actually aware. Even among the four sample groups which are geographically close to each other, there is notable variation. It would be interesting to see the degree of variation between the studies in the Province of Ontario, Canada, and the Province of Saskatchewan, Canada. The aim of this study was to investigate the awareness of Alzheimer's disease among young adults in Saskatoon, Canada. A total of 37 individuals consented and completed a survey. While only 51% of participants believed that they were knowledgeable the disease, it turns out that 70% are well-aware of the disease. Coupled with the fact that only 19% of respondents had a family member affected by the disease, the young adult population seems to be adequately versed with the disease. It is important to note that, based on the sample size of this study, it seems that there is a lower occurrence of Alzheimer's disease in the Province of Saskatchewan compared to studies completed in the Province of Ontario. However, this should be interpreted with caution as this study only sampled a small cohort of young adults in Saskatoon and could hence easily be influenced by response bias. Future studies should look into repeating this study with a large sample size to determine if there is any difference in responses between subgroups, and verifying the results.

INTRODUCTION

The increasingly-common disease of dementia, in conjunction with comorbidities, can yield inadequate care and poor quality of life for patients [1-2]. Literature has suggested that while healthcare professionals can improve standard of care through deploying new assessment tools, family members may be able to help to a greater extent to simply being educated about the illness and its implications [3].

Chow et al. [4] conducted a study among young adults in London, Canada, to assess how knowledgeable they were with respect to the Alzheimer's disease. The results showed that 75% of the cohort was well-aware of the disease, although only 48% of young adults believed that they were knowledgeable. Additionally, only 31% of the population had a family member, to their knowledge, with Alzheimer's disease. It hence seems that the sampled population was adequately aware of the disease, in order to care for their affected family members.

A validation study was conducted in Kingston, Canada [5], and noted similar trends. Chow et al. [4] reported that 60% of young adults were knowledgeable, while only 58% of them believed so. A lower 38% had a family member with Alzheimer's disease, again suggesting that the population was well-aware of the disease.

Studies were also conducted among young adults in Toronto, Canada [6], and Ottawa, Canada [7]. Borean et al. [6] reported that 39% of young adults in Toronto had familial ties to the disease, and 40% and 60% of the population believed they were aware and were actually aware respectively. Viehweger et al. [7] noted that 46% of family members were afflicted by Alzheimer's disease, and 69% and 85% believed they were knowledgeable and were actually knowledgeable, respectively in Ottawa.

These studies all revealed a similar trend that young adults are adequately aware of the disease. However, there still exists variation between the studies in the proportion of individuals who have a family member affected, who believed they are aware, and who are actually aware. Even among the four sample groups which are geographically close to each other, there is notable variation. It would be interesting to see the degree of variation between the studies in the Province of Ontario, Canada, and the Province of Saskatchewan, Canada. The aim of this study was to investigate the awareness of Alzheimer's disease among young adults in Saskatoon, Canada.

SURVEY METHOD

A survey, the same as that used by Chow et al. in London [4], was used to determine the awareness of young adults in Saskatchewan, Canada, see chapter 2 [8]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [8]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [8]; only those who recorded Saskatoon, Canada as their place of residence were included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [8]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member

affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [8].

The primary objective of the survey was to determine the awareness of Alzheimer's disease regardless of demographics (age, sex and other background). Secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The six items - 1 reflection and 5 knowledge questions - on page 3 were presented using descriptive statistics. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's, only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups - ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

OUTCOMES

A total of 37 individuals consented and completed the survey. 51% remained neutral with respect to assessing themselves as knowledgeable about the disease, while 41% believed they were knowledgeable and 8% remarked they were not well-aware. The majority of participants (73%) correctly answered that Alzheimer's is a subtype of dementia, while 5% incorrectly answered the question and 22% admitted they were unsure. Only 5% of respondents incorrectly believed that Alzheimer's is part of the normal aging process, while 92% correctly identified it was not part of the process and 3% indicated they did not know. All of those (95%) who attempted to answer the question pertaining to progression over time correctly reasoned that Alzheimer's does worsen over time. An overwhelming majority (92%) responded that there was no cure for Alzheimer's, with 3% and 5% incorrectly remarking and withholding an answer, respectively. Only 24% of respondents correctly recognized that Alzheimer's is a leading cause of death, with 54% incorrectly identifying that it is not, and 22% deciding not to answer. Overall, 70% of respondents were knowledgeable with respect to Alzheimer's disease, with 22% having satisfactory knowledge and 8% having poor knowledge (see Table 1).

Not Sure	8 (22%)
Overall Score	
Poor (1-2)	3 (8%)
Satisfactory (3)	8 (22%)
Knowledgeable (4-5)	26 (70%)

Under 20 Years Old vs 20 Years Old and above

Of the 37 respondents, 18 were under the age of 20 years old and 19 were 20 years old or older. There seems to be a trend that the older cohort believed that they were indeed more knowledgeable than the younger group ($p = 0.1598$), with 53% and 28%, respectively, remarking that they believe they are knowledgeable. The younger and older cohort identified that Alzheimer's is a subtype of dementia at a 78% and 68% rate, respectively ($p = 0.8411$). 95% and 89% of the older and younger cohort, respectively, correctly remarked that Alzheimer's is not a normal process of aging ($p = 0.3544$). 100% of the younger and 90% of the older group answered that Alzheimer's does worsen over time ($p = 0.4865$), while 94% and 90% of the two cohorts respectively responded that there is no cure for Alzheimer's disease ($p = 0.4865$). The vast majority of both cohorts (56% of those below 20 years old, and 53% of those 20 years old and above) incorrectly responded that Alzheimer's is not a leading cause of death ($p = 0.8240$). There was no difference in level of awareness between the two age groups, with 72% of the younger group and 68% of the older group deemed as knowledgeable based on their responses to the questionnaire ($p = 0.9999$) (see Table 2).

Males vs Females

There were 16 males and 21 females that responded to the questionnaire. 50% and 33% of males and females, respectively, indicated that they believe they are knowledgeable about the disease. 69% and 76%, respectively, correctly remarked that Alzheimer's disease is a form of dementia ($p = 0.3647$), while 88% and 95%, for the same groups respectively, noted that Alzheimer's is not part of the normal aging process ($p = 0.1802$). Only 1 male (6%) and 1 female (5%) did not answer correctly that Alzheimer's worsens over time ($p = 0.9999$). 94% of males and 90% of females identified that there was no cure for Alzheimer's disease ($p = 0.9999$). There seems to be a trend that females are more aware that Alzheimer's is a leading cause of death as opposed to males (24% for females vs 19% for males; $p = 0.1318$). Males (75%) and females (67%), overall, were equally aware about Alzheimer's disease ($p = 0.4234$) (see Table 3).

Affected vs Not Affected

Only 7 of the 37 respondents had a family member with Alzheimer's disease, to the knowledge of the participants. There seems to be a trend that those with family members afflicted by the disease believe they are more knowledgeable (57% vs 37%) ($p = 0.3346$). 86% of those affected and 70% of those without a family member affected by Alzheimer's disease correctly acknowledged that Alzheimer's is a subtype of dementia ($p = 0.9999$). A higher proportion of those without a family member (97%) believed that Alzheimer's is not part of the normal process, while only 71% of those with family members afflicted by the disease had a similar response ($p = 0.0315$). 100% of those affected and 93% of those not affected correctly answered that Alzheimer's worsens over time ($p = 0.9999$), while 100% and 90% of the groups, respectively, correctly responded that there is no cure for Alzheimer's disease ($p = 0.9999$). There was a trend that those affected by Alzheimer's disease were more likely to acknowledge the Alzheimer's is a leading cause of death (57%) as opposed to those without family members affected by the disease (17%). Overall, there was no significant difference in awareness levels between the two groups ($p = 0.2856$) - 86% of those affected and 67% of those not affected were deemed knowledgeable based on how they answered the survey (see Table 4).

DISCUSSION

While only 51% of participants believed that they were knowledgeable the disease, it turns out that 70% are well-aware of the disease. Coupled with the fact that only 19% of respondents had a family member affected by the disease, the young adult population seems to be adequately versed with the disease. This trend is similar to previous studies [4-7], and shows that young adults in the Province of Saskatchewan are also very aware of Alzheimer's disease.

This study also validates the conclusions of two [5, 7] of four [4-7] past studies that there was no difference between males and females with respect to knowledgeability. This may be

due to low statistical power as a consequence of the sample size, as noted in the other two studies [5, 7].

Table 2. Awareness of young adults by age

Overall Score Poor (1-2) Satisfactory (3) Knowledgeable (4-5)	 2 (12%) 2 (12%) 12 (75%)	 1 (5%) 6 (29%) 14 (67%)	0.4234

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 7)	Not Affected (n = 30)	p-value
Self-belief of being knowledgeable Yes Neutral No	 4 (57%) 2 (29%) 1 (14%)	 11 (37%) 17 (57%) 2 (7%)	0.3346
Alzheimer's is a subtype of dementia True False Not Sure	 6 (86%) 0 (0%) 1 (14%)	 21 (70%) 2 (7%) 7 (23%)	0.9999
Alzheimer's is normal with respect to aging True False Not Sure	 2 (29%) 5 (71%) 0 (0%)	 0 (0%) 29 (97%) 1 (3%)	0.0315
Alzheimer's worsens over time True False Not Sure	 7 (100%) 0 (0%) 0 (0%)	 28 (93%) 0 (0%) 2 (7%)	0.9999
No cure to Alzheimer's True False Not Sure	 7 (100%) 0 (0%) 0 (0%)	 27 (90%) 1 (3%) 2 (7%)	0.9999
Alzheimer's is leading cause of death True False Not Sure	 4 (57%) 3 (43%) 0 (0%)	 5 (17%) 17 (57%) 8 (27%)	0.0701
Overall Score Poor (1-2) Satisfactory (3) Knowledgeable (4-5)	 1 (14%) 0 (0%) 6 (86%)	 2 (7%) 8 (27%) 20 (67%)	0.2856

It is important to note that, based on the sample size of this study, it seems that there is a lower occurrence of Alzheimer's disease in the Province of Saskatchewan compared to studies completed in the Province of Ontario. However, this should be interpreted with caution as this study only sampled a small cohort of young adults in Saskatoon and could hence easily be influenced by response bias.

This study has its limitations. The sample size of this study could have decreased statistical power when detecting for differences. Also, there exists the possibility of cheating when completing the quiz portion of the survey, which would lead to an artificially higher proportion of individuals who would be knowledgeable.

In conclusion, 70% of young adults in Saskatchewan, Canada, are aware of Alzheimer's disease, although only 51% believed that they are knowledgeable. Given that 19% of young adults have a family member affected by the illness, it seems that young adults are adequately aware of the disease that their family members are affected by. Future studies should look into repeating this study with a large sample size to determine if there is any difference in responses between subgroups and verifying the results

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

Many symptoms of Alzheimer's are not recognized by the general population until later stages of the disease. One possible reason behind this may be that people are not aware enough about dementia and its consequences. In order to measure the level of awareness amongst people in several cities, numerous surveys were conducted on Alzheimer's awareness. A very similar study was conducted in Montreal, Canada, in order to further assess the general trends in Alzheimer awareness. 36 participants filled out the survey; 19 were under 20 years old and 17 were 20 years old and older; 7 males and 29 females responded to the survey; 14 had a family member affected by the disease while 22 did not. The young adults in Montreal were much more knowledgeable (78% scoring at four or above points) than they believed themselves to be (53% thought of themselves as knowledgeable). The results validate the general trend from prior studies that young adults are well-aware, given that 78% are knowledgeable compared to only 39% affected by the disease. The data herein validates prior general trends detailed in published literature. Although the population is well-aware, it is far from perfect; studies should look into how awareness can be increased further.

INTRODUCTION

Alzheimer's is a subtype and common form of dementia that affects the quality of life of many seniors. In 2013, it was the cause of 84,767 deaths in the United States, making it the 6th highest cause of death in the country [1]. Although specific causes of the disease remain unclear, certain trends have been observed in the population. For example, it has been found that populations with lower levels or a lack of education are more likely to develop Alzheimers [2].

Many symptoms of Alzheimer's are not recognized by the general population until later stages of the disease. One possible reason behind this may be that people are not aware enough about dementia and its consequences. In order to measure the level of awareness amongst people in several cities, numerous surveys were conducted on Alzheimer's awareness [3-6]. A study conducted in London, Canada, showed that while only 48% of participants believed themselves to be knowledgeable about the disease, 75% proved to be so based on the evaluation system in the study [7]. A trend indicating that having a family member with Alzheimer's does not correlate with general knowledge about the disease was observed in prior studies [3-6]. A very similar study was conducted in Montreal, Canada, in order to further assess the general trends in Alzheimer awareness.

OUR STUDY

A survey was created to measure the awareness of young adults in Montreal, Canada, see chapter 2 [8]. The first page had a consent form for the study; participants could enter their email to receive a copy of the consent form [8]. Afterwards, the survey contained three questions regarding demographics, including the participant's primary place of residence, age and sex [8]; only those who recorded Montreal, Canada, as their place of residence were included in this study. The subsequent page had six questions; the first was a reflection question and the others were knowledge-based questions - a quiz about Alzheimer's disease [8]. The last page of the survey asked participants about their family history with Alzheimer's disease- whether, to their knowledge, they have/had a family member affected by Alzheimer's; and how often they visit their relative [8].

The main purpose of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). The secondary objectives were to determine whether there were any differences across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The analysis was similar to that conducted by Chow et al. [7]. Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they answered correctly, with the right answers being: Alzheimer's disease is a form of dementia - True;

Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a significant difference between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

FINDINGS

36 participants filled out the survey. 53% of them believed they were knowledgeable about Alzheimer's disease, 42% were neutral and the remaining 6% were not confident about their knowledge. 81% of participants correctly chose that Alzheimer's is a subtype of dementia, 8% thought it was not and 11% were unsure. Most of the participants, 94%, believed that Alzheimer's is normal with respect to aging while 6% disagreed. 97% of participants stated that Alzheimer's worsens over time while 3% were unsure. Again, a majority of respondents (94%) chose that there was no cure to Alzheimer's, 3% disagreed and 3% were unsure. 22% of participants reported that Alzheimer's is a leading cause of death, 47% believed it was not and 31% were unsure. Overall, 78% of participants were knowledgeable about the disease, 14% had a satisfactory level of knowledge (answered 3 questions correctly) while 8% had relatively poor knowledge (only answered 1-2 questions correctly) about Alzheimer's (see Table 1).

Under 20 Years Old vs 20 Years Old and above

Of the 36 respondents, 19 were under 20 years old and 17 were 20 years old and older. 42% of the younger cohort believed they were knowledgeable about the disease while 65% of the older cohort did ($p = 0.3337$). 79% and 82% of the younger and older cohort respectively said that correctly identified that Alzheimer's is a subtype of dementia ($p = 0.9999$). 95% of the younger cohort and 94% of the older participants reported that Alzheimer's is not normal with respect to aging ($p = 0.9999$). 95% and 100% of the younger and older age cohort respectively believed that Alzheimer's worsens over time ($p = 0.9999$). 95% of those under 20 years old and 94% of those older than 20 years old and older stated that there is no cure to Alzheimer's ($p = 0.7286$). 21% of the younger cohort and 24% of the older cohort chose that Alzheimer's is the leading cause of death ($p = 0.2931$). In summary, 79% of the younger cohort and 76% of the older cohort were knowledgeable about the disease, meaning they answered 4-5 questions correctly ($p = 0.8600$) (see Table 2).

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 36)
Self-belief of being knowledgeable	
Yes	19 (53%)
Neutral	15 (42%)
No	2 (6%)
Alzheimer's is a subtype of dementia	
True	29 (81%)
False	3 (8%)
Not Sure	4 (11%)
Alzheimer's is normal with respect to aging	
True	34 (94%)
False	2 (6%)
Not Sure	0 (0%)
Alzheimer's worsens over time	
True	35 (97%)
False	0 (0%)
Not Sure	1 (3%)
No cure to Alzheimer's	
True	34 (94%)
False	1 (3%)
Not Sure	1 (3%)
Alzheimer's is leading cause of death	
True	8 (22%)
False	17 (47%)
Not Sure	11 (31%)
Overall Score	
Poor (1-2)	3 (8%)
Satisfactory (3)	5 (14%)
Knowledgeable (4-5)	28 (78%)

Knowledgeable (4-5)	15 (79%)	13 (76%)	

Males vs Females

There were 7 males and 29 females who responded to the survey. 29% of males had self-belief of their knowledge regarding the disease, while 59% of the females were confident in their knowledge ($p = 0.2194$). 43% of males and 90% of females stated that Alzheimer's is a subtype of dementia ($p = 0.0192$), which is statistically significant. 86% of males and 97% of females stated that Alzheimer's is not normal with respect to aging ($p = 0.3556$). 86% of males and all of the female respondents commented that Alzheimer's worsens over time ($p = 0.1944$). 71% of males and 100% of the females said that there is no cure to Alzheimer's ($p = 0.0333$). 57% of males said that Alzheimer's is not a leading cause of death while 45% of females thought the same ($p = 0.9999$). Overall, only 29% of the male respondents answered 4-5 questions correctly while all of the female respondents had a high knowledge of Alzheimer's disease ($p < 0.0001$) (see Table 3).

Table 3. Awareness of young adults by sex

Evaluation Metric	Male (n = 7)	Female (n = 29)	p-value
Self-belief of being knowledgeable			0.2194
Yes			
Neutral	2 (29%)	17 (59%)	
No	4 (57%)	11 (38%)

Satisfactory (3)	2 (29%)	0 (0%)	
Knowledgeable (4-5)	2 (29%)	29 (100%)	

Affected vs Not Affected

Of all the respondents, 14 had a family member affected by the disease while 22 did not. 71% of those affected and 41% of those who weren't believed that they were knowledgeable

about the disease ($p = 0.1700$). 86% and 77% of those affected and not affected respectively said that Alzheimer's is a subtype of dementia ($p = 0.4676$). All the participants who were affected and 91% of those who weren't affected said that Alzheimer's is not normal with respect to aging ($p = 0.5111$). All of the participants who were affected and 95% of those who weren't, commented that Alzheimer's worsens over time ($p = 0.9999$). 100% and 91% of those affected and not affected respectively said there was no cure to Alzheimer's ($p = 0.9999$). 43% of those affected said Alzheimer's is a leading cause of death while 9% of those who weren't affected said the same ($p = 0.0757$). 86% of those affected were quite knowledgeable and 73% of those who weren't affected were equally knowledgeable ($p = 0.4178$) (see Table 4).

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 14)	Not Affected (n = 22)	p-value
Self-belief of being knowledgeable			0.1700
Yes

Knowledgeable (4-5)	12 (86%)	16 (73%)	

DISCUSSION

The young adults in Montreal were much more knowledgeable (78% scoring at four or above points) than they believed themselves to be (53% thought of themselves as knowledgeable). This difference is much greater than Chow et al. [9] presented on North Carolina, where 53% of participants believed themselves to be knowledgeable and 58%

actually were. The results validate the general trend young adults are well-aware [2-6, 9], given that 78% are knowledgeable compared to only 39% affected by the disease.

In general, it appears that females have a significantly higher awareness of the fact that Alzheimer's is a subtype of dementia (90% answered correctly), as only 43% of males gave the correct response. Males seem to be much more inclined to believe that a cure for Alzheimer exists or are not sure (29%), while females all agree that no such cure exists. Most significantly, 100% of females were deemed knowledgeable based on their answers, yet only 29% of males were similarly branded. This trend validates the observations by Chow et al. in London, Canada [7]. These disparities may stem from a varying levels of interest in personal and family health, as well as interests of these gender cohorts.

Furthermore, those individuals who have family members affected by the disease appear to be more knowledgeable about the fact that Alzheimer's is a leading cause of death, as opposed to those unaffected (43% vs. 9%). This statistic may be due to the fact that these people are much more exposed to information about the disease as a result of discussions regarding the family members' treatment.

This study was not without limitations. In order to be able to determine significant differences between groups as opposed to trends, a much larger sample size would have been ideal. Perhaps a larger sample size could have been acquired had an email address not been required in order to complete the survey. Additionally, due to the online nature of the survey, the participants may have resorted to using outside resources to answer certain questions. Though this is unavoidable with such a medium, the fact that participants were described the nature of the assessment and asked to answer honestly may have mitigated this issue.

In conclusion, the data collected shows that the young adults in Montreal are more knowledgeable about Alzheimer's than they believe themselves to be. Additionally, females seems to be better informed about the details of the disease than males, perhaps as a result of varying amounts of involvement in Alzheimer's education and involvement in family treatment. The data herein validates prior general trends detailed in published literature. Although the population is well-aware, it is far from perfect; studies should look into how awareness can be increased further.

ACKNOWLEDGMENTS

We would like to thank all of those who participated in the questionnaire. Anna Rzepka and Drew Hollenberg contributed equally to the preparation of this manuscript, and are considered co-first authors.

Infinitas Research Group, London, Ontario, Canada

ABSTRACT

Family members can play a pivotal role in the care of Alzheimer's patients by increasing their knowledge and awareness of the disease. Studies have been conducted around the globe by a research group based out of London, Canada, to look into the awareness levels of young adults. Even though a similar trend was observed in all of the different geographical regions, there exists variation between distinct locations. The aim of this investigation was to study the awareness level of young adults in North Carolina, United States, with respect to Alzheimer's disease. A survey was designed to evaluate the awareness of young adults, and was completed by 38 respondents. 58% of the young adults in North Carolina were knowledgeable. This is a higher proportion than the self-perceived level and the percentage of the population that have a family member personally affected by the disease, both of which is 53%. This study did reveal that there seems to be a difference in awareness level between individuals with and without a family member suffering from Alzheimer's, which is a novel finding. Future studies should look into determining whether this was an anomaly, and perhaps explain why this finding may exist.

INTRODUCTION

There have been many studies completed that look into tools to improve quality of life and standard of care for Alzheimer's and dementia patients. While healthcare professionals have gone to great extents to improve quality of care, family members can also play a great role by increasing their knowledge and awareness of the disease [1].

Studies have been conducted by a research group based out of London, Canada, to look into the awareness levels of young adults [2-10]. The first three studies looked to identify trends among the cohort in London, Kingston, and Toronto (all in Canada) [2-4]. In London [2], it was found that 75% of the population was well-aware of the disease, but only 48% and 31% believed they were knowledgeable and had a family member affected by the disease, respectively. The study carried out in Kingston noted a similar trend, with 60% knowledgeable, 58% believing they were knowledgeable, and only 38% of the group having a family member afflicted by the disease. Borean et al. noted that, among young adults of Toronto, 39% had familial ties and 40% acknowledged they were knowledgeable, which is lower than the 60% of those who actually are well-aware [4].

Follow-up studies were conducted in other cities in the Canadian Province of Ontario [5, 6, 10], Canadian Province of Saskatchewan [7], Dublin, Ireland [8], and Asia [9]. The trend was verified in all but one study [5] - in that study, there was not an observation that awareness level was higher than the proportion of those affected by the disease, but this may have been an anomaly due to the sample size.

Even though the trend was observed in all of the different geographical regions, there exists variation between distinct locations. In Asia, for example, the proportion of those who were well-aware and the proportion of those who were affected by the illness was equal; this finding contrasts with prior studies that indicated that a higher proportion were aware compared to the proportion who was affected by the disease [9]. The aim of this study was to discover the awareness level of young adults in North Carolina, USA, with respect to Alzheimer's disease.

OUR SURVEY

A survey was designed to evaluate the awareness of young adults in North Carolina, USA, among other places, see chapter 2 [2, 11]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [11]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [11]; only those who recorded North Carolina as their place of residence was included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [11]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [11].

The primary objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). The secondary objectives were to determine whether there existed any difference in knowledge across

different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The same statistical analysis that was conducted for the London study, and the other studies, [2-9] was carried out in this setting. Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

OUR FINDINGS

38 individuals completed the survey, of which 53% believed that they were knowledgeable about Alzheimer's disease. 71% correctly responded that Alzheimer's is a subtype of dementia, 89% accurately noted that Alzheimer's is not normal with respect to aging, 89% remarked that Alzheimer's does worsen over time, 79% mentioned that there is no cure to Alzheimer's, and only 34% of the population correctly noted that Alzheimer's is a leading cause of death. Overall, 58% of the sample population were deemed knowledgeable, 32% had satisfactory knowledge, and 11% had poor knowledge (see Table 1).

Under 20 Years Old vs 20 Years Old and above

17 respondents were under the age of 20 years old, and the remaining 21 respondents identified themselves as 20 years old or older. 59% of the younger and 48% of the older group classified themselves as knowledgeable about the disease ($p = 0.5759$). While 65% of the younger cohort responded that Alzheimer's is a subtype of dementia, a higher 76% of the older cohort responded to the same answer ($p = 0.2306$). There was no difference in response between the groups with respect to whether Alzheimer's is a normal process of aging; 94% and 86% of the two groups, respectively, answered that it is not normal ($p = 0.9999$). All of those under 20 years old answered that Alzheimer's worsens over time, while 81% of older

adults similarly responded to the question ($p = 0.2383$). 88% and 47% of the younger group answered ‘True’ to the statements that there is no cure to Alzheimer’s and that Alzheimer’s is a leading cause of death, respectively. There were no difference between the overall knowledge scores of the younger and older cohort ($p = 0.7144$), with 65% and 52% of the groups, respectively, considered knowledgeable (see Table 2).

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 38)
Self-belief of being knowledgeable Yes Neutral No	20 (53%) 16 (42%) 2 (5%)

Alzheimer's is leading cause of death True False Not Sure	8 (47%) 4 (24%) 5 (29%)	5 (24%) 11 (52%) 5 (24%)	0.1945
Overall Score Poor (1-2) Satisfactory (3) Knowledgeable (4-5)	1 (6%) 5 (29%) 11 (65%)	3 (14%) 7 (33%) 11 (52%)	0.7144

Males vs Females

Of the 38 respondents, 11 identified as males and 26 recognized themselves as females. There seems to exist no difference in self-belief levels ($p = 0.4109$), with 9% of males and 4% of females remarking that they are not knowledgeable. There were no differences in responses between males and females with respect to questions probing about whether Alzheimer's is a subtype of dementia (64% for males vs 73% of females agreed; $p = 0.5283$), whether Alzheimer's worsens over time (82% vs 92% agree; $p = 0.4489$), and whether Alzheimer's is a leading cause of death (36% of males and 39% of females were unsure; $p = 0.7438$). Females were more aware that Alzheimer's is not part of the normal aging process, with 96% compared to 73% of males recognizing the fact ($p = 0.0212$). Females were also more aware that there was no cure for Alzheimer's (92% vs 46% for males; $p = 0.122$). Overall, females are more knowledgeable compared to males, with 65% (vs 36% for males) deemed knowledgeable ($p = 0.0084$) (see Table 3).

Affected vs Not Affected

20 of the 38 respondents had a family member affected by Alzheimer's disease, while 18 did not. Those with family members affected by Alzheimer's seem to be more confident in their awareness level, with 70% of affected compared to 33% of unaffected stating that they are knowledgeable ($p = 0.665$). There were no differences in any of the component questions between the two cohorts; those who had an affected member answered that Alzheimer's is a subtype of dementia 80% of the time (compared to 61%; $p = 0.4604$), Alzheimer's is not part of the normal aging process at 95% (vs 83%; $p = 0.0967$), Alzheimer's worsens over time at 90% (compared to 89%; $p = 0.7915$), Alzheimer's has no cure at 85% (compared to 72%; $p = 0.6223$), and that Alzheimer's is a leading cause of death at 27% (compared to 39%;

$p = 0.7439$). While 60% of those who had a family member affected by the disease were knowledgeable, 56% of those without an affected member were deemed knowledgeable ($p = 0.0872$) (see Table 4).

Table 3. Awareness of young adults by sex

Evaluation Metric	Male (n = 11)	Female (n = 26)	p-value

Knowledgeable (4-5)	12 (60%)	10 (56%)	

DISCUSSION

The initial self-reported knowledge level of the young adults of North Carolina was noted to be 53%, which is slightly lower than the actual awareness level of 58%. The proportion of the population with a family member affected by the disease was also 53%, suggesting that the population is hence adequately about the disease such that it can care for their family members.

This study revealed that there seems to be a trend that females are more knowledgeable than males with respect to the disease, and also that those with a family member affected by the disease are more aware. The observed difference between sexes validates a previous finding by Borean et al. among young adults in Toronto [4]. However, the novel finding of a difference in awareness between cohorts with affected/unaffected family members has not been found in prior studies [2-9]. Future studies should look to see whether the finding in this study is an anomaly.

This study was not without limitations, as with the prior studies of this nature [2-9]. The sample size of the study had good quality and quantity at times, but only lead to detection of trends rather than significant differences at other points - a large sample size would have mitigated this issue. Additionally, due to the nature of the quiz (online survey), there exists the possibility that participants could have employed reference resources to assist in their answers - this is unfortunately avoidable due to the medium of the survey, but was hopefully minimized by assuring participants that the quiz is an assessment of knowledge and should be answered honestly without help.

In conclusion, 58% of the young adults in North Carolina were knowledgeable. This is a higher proportion than the initial self-reported level and the percentage of the population that have a family member personally affected by the disease, both of which is 53%. This study did reveal that there seems to be a difference in awareness level between individuals with and without a family member suffering from Alzheimer's, which is a novel finding. Future studies

should look into determining whether this was an anomaly, and perhaps explain why this finding may exist.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

Alzheimer's has no cure, but increased knowledge of the disease among family members of patients suffering from the disease may lead to improved standard of care and quality of life. The aim of this study was to examine Alzheimer's disease awareness levels in young adults in New York State, USA. A survey was designed to evaluate the awareness of this age group. The main objective of the survey was to determine the awareness of Alzheimer's disease across all young adults (regardless of age, sex and other background). Other objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older individuals, and between those with and without family members with Alzheimer's disease. 51% of the population had a family member affected by Alzheimer's disease. While only 47% of individuals believed that they were knowledgeable about the disease, 60% of participants were deemed to be relatively well-aware. There is a trend to suggest that young females in New York State are more well-informed about the disease than young males. There were statistically significant differences in awareness levels between individuals who had family members affected by Alzheimer's and those who had no known affected family members.

INTRODUCTION

Alzheimer's disease is neurodegenerative disease that is associated with comorbidities and results in a subpar quality of life [1]. Alzheimer's has no cure, but increased knowledge of the disease among family members of patients suffering from Alzheimer's may lead to improved standard of care and quality of life [2].

Chow et al. [3] examined disease awareness among young adults in London, Canada. Only 48% of the cohort believed that they were knowledgeable about the disease, but a full three-quarters of all participants were well-aware. Less than one-third of the sample population actually had a family member affected by the disease, which, when considering overall awareness levels, might indicate a trend that young adults are adequately aware of Alzheimer's disease.

Several follow-up studies [4-8] have been conducted to explore this trend in different geographic regions. 60% of participants in a study in Kingston were knowledgeable, despite only 38% of the cohort believing to have a family member affected by the disease [4]. In Toronto, Borean et al. [5] reported similar results; 60% of young adults were well-informed regarding the disease's implications, with only 39% reporting familial ties to the disorder and 40% believing that they were knowledgeable.

While similarities exist between different geographic regions, there are still variations between distinct demographics. The aim of this study was to examine Alzheimer's disease awareness levels in young adults in New York State, United States.

SURVEY

A survey was designed to evaluate the awareness of young adults in New York State [9]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form, see chapter 2 [9]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age, and sex [9]; only those who recorded New York State as their place of residence were included in this study. The third page had six questions - the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [9]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [9].

The main objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). Other objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The same statistical analysis conducted by Chow et al. [3] was executed. Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's, only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

SURVEY FINDINGS

47 individuals consented and completed the questionnaire. 47% reported self-belief of being knowledgeable about the disease, while 43% reserved judgment regarding their knowledge and only 11% believed that they were not knowledgeable. Most participants (64%) correctly identified that Alzheimer's is a subtype of dementia, 85% understood that Alzheimer's is not normal with respect to aging, 96% were aware that Alzheimer's worsens over time, and 87% acknowledged that there is no cure to the disease. Only 28% of participants correctly responded that Alzheimer's disease is a leading cause of death. Overall, 60% of participants were knowledgeable, while 26% and 15% had satisfactory and poor awareness, respectively (see Table 1).

Under 20 Years Old vs 20 Years Old and above

39 of the 47 participants were under 20 years old, and 8 were 20 years old and older. Both cohorts have similar self-beliefs regarding personal awareness levels; 44% of individuals under 20 years old believed that they were knowledgeable about Alzheimer's compared to 63% of participants over 20 years old ($p=0.5406$). While not statistically significant, there is a trend to suggest that individuals under 20 years old are more knowledgeable of the fact that Alzheimer's disease is a form of dementia – 69% of individuals under 20 years old correctly responded to this statement, compared to only 38% of participants older than 20 years old ($p=0.1297$). Both age cohorts were equally aware that Alzheimer's disease is not normal with respect to the aging process, with 82% and 100% of the individuals in the under 20 years old and over 20 years old age groups correctly answering this question ($p=0.9999$). Individuals under 20 years old are more well-informed that

Alzheimer's worsens over time, with all (100%) participants in this cohort correctly identifying this statement as true, compared to just 75% of individuals older than 25 years old ($p=0.0259$). With respect to the question regarding if there is a cure to Alzheimer's, younger individuals are more aware that there is no cure to the disease; 92% of individuals in the under 20 years old cohort correctly answered this question, compared to only 63% of participants in the older group ($p=0.0069$). Only 28% and 25% of individuals in the under 20 years old and 20 years old or older cohorts correctly identified that Alzheimer's is a leading cause of death; no difference was noted ($p=0.1634$). Overall, both age groups were equally knowledgeable regarding Alzheimer's disease and its implications, with 64% and 38% of individuals in the younger and older cohorts, respectively, being generally knowledgeable about the disease ($p=0.3379$) (see Table 2).

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 47)
Self-belief of being knowledgeable	
Yes	22 (47%)
Neutral	20 (43%)
No	5 (11%)
Alzheimer's is a subtype of dementia	
True	30 (64%)
False	8 (17%)
Not Sure	9 (19%)
Alzheimer's is normal with respect to aging	
True	3 (6%)
False	40 (85%)
Not Sure	4 (9%)
Alzheimer's worsens over time	
True	45 (96%)
False	2 (4%)
Not Sure	0 (0%)
No cure to Alzheimer's	
True	41 (87%)
False	3 (6%)
Not Sure	3 (6%)
Alzheimer's is leading cause of death	
True	13 (28%)
False	22 (47%)
Not Sure	12 (26%)
Overall Score	
Poor (1-2)	7 (15%)
Satisfactory (3)	12 (26%)
Knowledgeable (4-5)	28 (60%)

Males vs Females

11 respondents were female, 35 were male, and 1 preferred not to select a binary option. 45% of males and 46% of females believed that they were knowledgeable about Alzheimer's; no difference was noted ($p=0.9999$). 55% of males and 66% of females correctly identified that Alzheimer's is a subtype of dementia ($p=0.7894$). There is a strong trend to suggest that females are more aware than males that Alzheimer's is not a normal part of the aging process; while 91% of females correctly identified that Alzheimer's is abnormal, only 64% of males

correctly identified that the disorder is not a normal part of aging ($p=0.0689$). Females may also be more well aware than their male counterparts that Alzheimer's worsens over time; 100% of females correctly identified this, compared to only 82% of males ($p=0.0531$). There is a statistically significant difference between the sexes in terms their awareness of the incurable nature of the disease, with females being more knowledgeable than males; 94% of females correctly identified that there is no cure to Alzheimer's, compared to just 64% of males ($p=0.0102$). Only 36% of males and 26% of females reported that Alzheimer's is a leading cause of death ($p=0.8272$). While not statistically significant, there is a strong trend to suggest that females are more knowledgeable than males in terms of overall levels of disease awareness; 66% of females were knowledgeable about Alzheimer's disease while only 36% of males were well-informed ($p=0.0863$) (see Table 3).

Satisfactory (3)	9 (23%)	3 (38%)	
Knowledgeable (4-5)	25 (64%)	3 (38%)	

Affected vs Not Affected

24 individuals had family members who were affected by Alzheimer's, whereas 23 did not have a family member to their knowledge afflicted by this disease. There was a statistically significant difference in self-belief and actual knowledge. 71% of those with an

affected family member classified themselves as being knowledgeable, compared to just 22% of those without any familial ties ($p=0.0023$). While not statistically significant, there is a strong trend to suggest that people with affected family members are more well aware that Alzheimer's is a form of dementia than those without affected family members; 79% of participants in the affected cohort correctly identified this compared to 48% of those in the unaffected group ($p=0.0889$). Both groups are equally well-aware that Alzheimer's is not normal with respect to aging, with 92% and 78% of individuals in the affected and not affected cohort, respectively, correctly identifying the abnormality associated with the disorder ($p=0.4016$). 100% of participants in the affected cohort and 91% of those in the unaffected cohort correctly identified that the disease worsens over time; no difference was noted ($p=0.2340$). Both cohorts were equally well aware that there is no cure to Alzheimer's, with 96% of those in the affected group and 78% of those in the unaffected group responding correctly to this question ($p=0.1305$). With respect to the question that tests knowledge of the lethality of Alzheimer's, statistically significant differences exist between the two groups; 33% of those in the affected group were well aware that Alzheimer's is a leading cause of death, while only 22% of participants in the unaffected cohort were able to correctly identify this ($p=0.0021$). Overall, participants in the affected group are more knowledgeable than individuals who have not had family members affected by the disease; 75% of those in the affected cohort were deemed to be generally knowledgeable about the disease, compared to just 43% of those in the unaffected group ($p=0.0072$) (see Table 4).

DISCUSSION

Only 47% of individuals believed that they were knowledgeable with respect to Alzheimer's disease, but the proportion of individuals who are actually knowledgeable is significantly higher (60%). Given that approximately half (51%) of respondents actually have had family members affected by the disease, it is likely that the young adult population in New York State is generally well-aware about Alzheimer's disease and its implications.

This study yielded results similar to prior studies at different geographic locations in that overall awareness levels were larger than the proportion of individuals with affected members [2-6]. This is reassuring in that it strongly suggests that the general young adult population possesses adequate awareness and knowledge about Alzheimer's disease. This study also appears to validate other previous findings regarding sex differences [3, 5]. While not statistically significant, there is a strong trend to suggest that young females in New York State are generally more well-informed about the implications of the disease than young males. Further research should investigate why these sex differences exist, and what can be done to increase overall male awareness levels.

This study provides evidence that young adults with affected family members are more knowledgeable about the disease than their unaffected counterparts. This trend is interesting, but perhaps understandable given that an individual is probably more likely to be willing to

learn about a health condition which he or she has been readily exposed to. Future studies should search for validation of this trend in other geographic locations, and programs should be devised to better inform young adults without familial ties to the disease about its nature and implications.

This study was not without limitations. The sample size of the study had good quality and quantity at times, but only lead to detection of trends rather than significant differences at other points - a large sample size would have mitigated this issue. Additionally, there exists the possibility that participants could have employed reference resources to assist in their answers - this is unfortunately avoidable due to the medium of the survey, but was hopefully minimized by assuring participants that the quiz is an assessment of knowledge and should be answered honestly without help.

In conclusion, 51% of the population had a family member affected by Alzheimer's disease. While only 47% of individuals believed that they were knowledgeable about the disease, 60% of participants were deemed to be relatively well-aware. There is a trend to suggest that young females in New York State are more well-informed about the disease than young males. There were statistically significant differences in awareness levels between individuals who had family members affected by Alzheimer's and those who had no known affected family members. Follow up studies should look to validate these trends in different regions across the globe.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

There have been numerous studies published that have looked into the awareness level of Alzheimer's disease amongst the young adult population. The trend seems to be similar in different geographic regions, but there does exist variation between data. It would be interesting to see how different regions vary, and perhaps advocate for positive change, if necessary. The aim of this study was to examine the awareness level of young adults in Dublin, Ireland, with respect to Alzheimer's disease. A survey was designed to evaluate the awareness of young adults. A total of 36 people consented and completed the questionnaire; 18 were under 20 years old and 18 were 20 years old or older, 10 were male and 26 were female, while 12 (29%) had family members affected by the disease and 24 (71%) did not. 77% of the participants were well-aware of the disease, although only 44% believed they were. It seems that the young adult population is adequately aware of the disease, and may be able to improve standard of care as a result of higher knowledgeability. Follow-up studies should look into whether this trend transcends into other regions of the globe, and to determine how the high level of awareness can be mobilized to improve patient care.

* Corresponding Author's Email: rchow48@uwo.ca.

INTRODUCTION

While healthcare professionals have developed many novel tools to improve the standard of care for Alzheimer's patients, awareness and knowledge about the disease by family members could further improve the quality of life of patients [1]. There have been numerous studies published that have looked into the awareness level of Alzheimer's disease amongst the young adult population.

The first study published looked into the awareness level of young adults in London, Canada [2]. The study concluded that a favourable 75% of the cohort was well-aware of the disease, while only 48% believed that they were knowledgeable. When these statistics are interpreted in lieu of the fact that 31% of the sample population had a family member affected by Alzheimer's disease, there seems to be a trend that young adults are adequately aware of the disease.

Four follow-up studies were conducted among young adults across the Canadian Province of Ontario [3-6]. In Kingston, 60% of the population was knowledgeable, compared to the 58% that believed they were, while 38% of the population had a family member affected by the disease [3]. Among young adults in Toronto, 39% had familial ties and 40% believed they were knowledgeable, yet it turned out that 60% were well-aware of the disease [4]. A similar trend was noted among the young adult populations in Ottawa (46% with family members affected, 69% believed they were knowledgeable, and 85% were knowledgeable according to the assessment tool) [5].

Viehweger et al. [7] studied the awareness level among young adults in the Canadian Province of Saskatchewan. While they reported a similar trend - higher awareness level (70%) than perceived awareness (51%) as well as the portion of individuals with affected family members (19%) [7] - they showed some variation in their results. Based on the sample size of the study, there is a lower proportion of individuals with family members affected by Alzheimer's disease.

The trend seems to be similar in different geographic regions, but there does exist variation between data. It would be interesting to see how different regions vary, and perhaps advocate for positive change, if necessary. The aim of this study was to study the awareness level of young adults in Dublin, Ireland, with respect to Alzheimer's disease.

OUR STUDY

A survey was designed to evaluate the awareness of young adults in Dublin, Ireland, see chapter 2 [2, 8]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [8]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [8]; only those who recorded Dublin, Ireland, as their place of residence was included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [8]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their relative [8].

The primary objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). The secondary objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The same statistical analysis conducted for the London study [2] was carried out in this setting. Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

What Did We Find?

A total of 36 people consented and completed the questionnaire. Of these 36 participants, 47% reserved judgement about their belief of their knowledgeability, 44% believed that they are knowledgeable, and 8% acknowledged that they are not knowledgeable. 83% correctly identified that Alzheimer's disease is a subtype of dementia, while the remaining 17% of individuals, evenly-split, believed that Alzheimer's is not a subtype and reserved judgement. 3% were not sure whether Alzheimer's is a normal process with respect to aging, 16% incorrectly remarked that it was part of the normal aging process, and the remaining 81% accurately answered it was not normal. An overwhelming majority, 92%, recognized that Alzheimer's worsens over time, with 3% and 5% believing that it does not and are not sure, respectively. 88% of participants correctly answered that there is no cure to Alzheimer's, and 3% and 8% indicated there is a cure and that they were unsure. A majority of respondents noted that they are unsure whether Alzheimer's is a leading cause of death, while 25% and 22% incorrectly and correctly responded to the answer. Overall, 77% of participants were deemed knowledgeable, while 19% and 3% were noted as having satisfactory and poor knowledge, respectively (see Table 1).

Table 1. Awareness of all young adults

Evaluation Metric	All (n = 36)
Self-belief of being knowledgeable	
Yes	16 (44%)
Neutral	17 (47%)
No	3 (8%)
Alzheimer's is a subtype of dementia	
True	30 (83%)
False	3 (8%)
Not Sure	3 (8%)
Alzheimer's is normal with respect to aging	
True	6 (16%)
False	29 (81%)
Not Sure	1 (3%)
Alzheimer's worsens over time	
True	33 (92%)
False	1 (3%)
Not Sure	2 (5%)
No cure to Alzheimer's	
True	32 (88%)
False	1 (3%)
Not Sure	3 (8%)
Alzheimer's is leading cause of death	
True	8 (22%)
False	9 (25%)
Not Sure	19 (53%)
Overall Score	
Poor (1-2)	1 (3%)
Satisfactory (3)	7 (19%)
Knowledgeable (4-5)	28 (77%)

Table 2. Awareness of young adults by age

Evaluation Metric	Under 20 Years Old (n = 18)	20 Years Old and Older (n = 18)	p-value
Self-belief of being knowledgeable			0.9999
Yes	8 (44%)	8 (44%)

Overall Score			0.9999
Poor (1-2)	1 (5%)	0 (0%)	
Satisfactory (3)	3 (17%)	4 (22%)	
Knowledgeable (4-5)	14 (78%)	14 (78%)	

Under 20 Years Old vs 20 Years Old and above

Of the 36 participants, 18 people were under 20 years old and 18 individuals were 20 years old and older. There was no difference in self-belief level ($p=0.9999$), with 44% of both groups remarking that they are knowledgeable about Alzheimer's disease. There was also no difference in answers between the age groups with respect to whether Alzheimer's is a subtype of dementia ($p=0.9999$), with 83% of both groups correctly identifying that Alzheimer's disease is a subtype of dementia. It seems that the older cohort was more aware that Alzheimer's is not part of the normal aging process (88%, compared to 72%) ($p=0.1774$). There was also no difference in knowledge with respect to whether the disease worsens over time ($p=0.9999$); 5% of those under 20 years old and 5% of those 20 years and older are not too sure about the answer for the question. While 94% of those below 20 years old correctly recognized that there is no cure for Alzheimer's disease, only 83% of those 20 years and older similarly responded to the question ($p=0.2286$). For the question pertaining to whether Alzheimer's is a leading cause of death, 27% and 22% of those under and above 20 years old, respectively, incorrectly believed that it is not a leading cause of death ($p=0.7486$). Overall, there was no difference in knowledge level, with 78% of those under 20 years old and 78% of those 20 years old and above, being deemed knowledgeable ($p=0.9999$) (see Table 2).

Males vs Females

12 of the 36 respondents were male, with the other 24 identifying themselves as females. Males and females had similar self-belief levels ($p=0.5877$), with 42% of males and 46% of females proclaiming that they are knowledgeable. There was a trend that women are more aware that Alzheimer's is a subtype of dementia ($p=0.1032$), with 92% of females correctly remarking that it is a subtype of dementia as opposed to 66% of males. 83% and 79% of males and females, respectively, answered that Alzheimer's is not normal with respect to aging ($p=0.9999$). 83% of males and 96% of females answered that Alzheimer's worsens over time ($p=0.2527$). 92% of males and 88% of females recognized that there is no cure for Alzheimer's ($p=0.2011$). There was no difference in responses between males and females with respect to whether Alzheimer's is a leading cause of death ($p=0.3289$); 16% of males and 25% of females correctly remarked that Alzheimer's is a leading cause of death. Overall, 83% of males and 75% of females received a score of 4 or 5 out of 5, hence being classified as knowledgeable ($p=0.9999$) (see Table 3).

Affected vs Not Affected

Of the 36 participants, 10 have a family member affected by Alzheimer's disease to their knowledge. Those with family members affected Alzheimer's disease were more likely to rate themselves as knowledgeable (90% compared to 27%; $p=0.0024$). There was no difference in responses between the cohorts with respect to any of the five knowledge questions: Alzheimer's as a subtype of dementia (90% for affected vs 81% for those not affected correctly answered it is a subtype; $p=0.7928$); Alzheimer's as a normal process of

aging (70% vs 85%, respectively, properly answered it was not normal; $p=0.5103$); Alzheimer's worsens over time (90% and 92%, respectively, agreed with the statement; $p=0.3324$); cure for Alzheimer's (80% and 92%, respectively remarked that there is no cure; $p=0.4152$); Alzheimer's as a leading cause of death (30% and 19%, respectively, correctly identified it is a leading cause of death; $p=0.6926$). There was no difference in overall score between those with family members affected and not affected by the disease; 60% of those affected and 85% of those not affected by the disease received a score to be deemed as knowledgeable ($p=0.2066$) (see Table 4).

Table 3. Awareness of young adults by sex

Evaluation Metric	Male (n = 12)	Female (n = 24)	p-value
Self-belief of being knowledgeable			0.5877
Yes	5 (42%)	11 (46%)	
Neutral	7 (58%)	10 (42%)	
No	0 (0%)	3 (13%)	
Alzheimer's is a subtype of dementia			0.1032
True	8 (67%)	22 (92%)	
False	2 (17%)	1 (4%)	
Not Sure	2 (17%)	1 (4%)	
Alzheimer's is normal with respect to aging			0.9999
True			
False	2 (16%)	4 (16%)	
Not Sure	10 (83%)	19 (79%)	
	0 (0%)	1 (4%)	
Alzheimer's worsens over time			0.2527
True	10 (83%)	23 (96%)	
False	1 (8%)	0 (0%)	
Not Sure	1 (8%)	1 (4%)	
No cure to Alzheimer's			0.2011
True	11 (92%)	21 (88%)	
False	1 (8%)	0 (0%)	
Not Sure	0 (0%)	3 (12%)	
Alzheimer's is leading cause of death			0.3289
True	2 (16%)	6 (25%)	
False	5 (42%)	4 (16%)	
Not Sure	5 (42%)	14 (58%)	
Overall Score			0.9999
Poor (1-2)	0 (0%)	1 (4%)	
Satisfactory (3)	2 (17%)	5 (21%)	
Knowledgeable (4-5)	10 (83%)	18 (75%)	

DISCUSSION

While only 44% of participants believed that they were knowledgeable about Alzheimer's disease, their responses to the questionnaire showed that in fact 77% were well-aware of the disease. These results show that the trend reported by studies in Canada [2-7] are also observed among young adults in Dublin, Ireland.

The results revealed that only 29% of the population had a family member affected by Alzheimer's disease, which is lower than both the self-belief rate and the actual awareness rate. These results seem to indicate that the young adult population is adequately aware, as the

awareness level is higher than the incidence rate. The data validates the trend of all but one study [6], where the awareness level is higher than the incidence rate of Alzheimer's disease.

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 10)	Not Affected (n = 26)	p-value
Self-belief of being knowledgeable			0.0024
Yes	9 (90%)	7 (27%)	
Neutral	1(10%)	16 (62%)	
No	0 (0%)	3 (12%)	
Alzheimer's is a subtype of dementia			0.7928
True	9 (90%)	21 (81%)	
False	0 (0%)	3 (12%)	
Not Sure	1(10%)	2 (8%)	
Alzheimer's is normal with respect to aging			0.5103
True			
False	3 (30%)	3 (12%)	
Not Sure	7 (70%)	22 (85%)	
	0 (0%)	1 (4%)	
Alzheimer's worsens over time			0.3324
True	9 (90%)	24 (92%)	
False	1 (10%)	0 (0%)	
Not Sure	0 (0%)	2 (8%)	
No cure to Alzheimer's			0.4152
True	8 (80%)	24 (92%)	
False	1 (10%)	0 (0%)	
Not Sure	1 (10%)	2 (8%)	
Alzheimer's is leading cause of death			0.6926
True	3 (30%)	5 (19%)	
False	3 (30%)	6 (23%)	
Not Sure	4 (40%)	15 (58%)	
Overall Score			0.2066
Poor (1-2)	1 (10%)	0 (0%)	
Satisfactory (3)	3 (30%)	4 (25%)	
Knowledgeable (4-5)	6 (60%)	22 (85%)	

This study was not without limitations. The sample size of the study had good quality and quantity at times, but only lead to detection of trends rather than significant differences at other points - a large sample size would have mitigated this issue. Additionally, there exists the possibility that participants could have employed reference resources to assist in their answers - this is unfortunately avoidable due to the medium of the survey, but was hopefully minimized by assuring participants that the quiz is an assessment of knowledge and should be answered honestly without help.

In conclusion, 29% of the population had a family member affected by Alzheimer's disease. 77% of the participants were well-aware of the disease, although only 44% of them believed so. It seems that the young adult population is adequately aware of the disease, and may be able to improve standard of care as a result of higher knowledgeability. Follow-up studies should look into whether this trend transcends into other regions of the globe, and to determine how the high level of awareness can be mobilized to improve patient care.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

ABSTRACT

Family members of patients suffering from Alzheimer's disease may help healthcare professionals improve standard of care and hence quality of life by being knowledgeable about the disease. The aim of this study was to study the awareness level of young adults in Asia with respect to Alzheimer's disease. 14 individuals consented and completed a questionnaire, with their primary location of residence ranging from Taiwan to China to Dubai. 42% of the population had a family member affected by Alzheimer's disease. Exactly 42% of the participants were well-aware of the disease, although only 21% of them believed so. This trend is slightly different than those determined in previous studies, and this may be a result of the different geographical region and different education/awareness levels. Follow-up studies should look into whether this different trend transcends into other regions of the globe.

INTRODUCTION

Family members of patients suffering from Alzheimer's disease may help healthcare professionals improve standard of care and hence quality of life by being knowledgeable about the disease [1].

A study by Chow et al. [2] examined the awareness level of young adults in London, Canada. The study found that 75% of the cohort was well-aware of the disease, while only

* Corresponding Author's Email: rchow48@uwo.ca.

48% believed that they were knowledgeable. Given that 31% of the sample population had a family member affected by Alzheimer's disease, there seems to be a trend that young adults are adequately aware of the disease.

Multiple follow-up studies [3-8] have been conducted to validate the trend in different demographic regions. In Kingston, 60% of the population was knowledgeable, compared to the 58% that believed they were and the 38% who had a family member affected by the disease [3]. Borean et al. [4] also verified the trend, as while 39% had familial ties and 40% believed they were knowledgeable, it turned out that 60% were aware of the disease.

The trend seems to be similar in different geographic regions [8], but there exists variation between different regions. The aim of this study was to study the awareness level of young adults in Asia with respect to Alzheimer's disease.

OUR STUDY

A survey was designed to evaluate the awareness of young adults in Asia, see chapter 2 [2, 9]. The first page had a consent form for the study; participants had the option to enter their email and receive a copy of the consent form [9]. After consenting to the study, participants completed three questions to collect relevant demographics - primary place of residence, age and sex [9]; only those who recorded Asia as their place of residence were included in this study. The third page had six questions, with the first being a reflection question and the next five being knowledge-based questions - a quiz about Alzheimer's disease [9]. The last page of the survey asked participants whether, to their knowledge, they have/had a family member affected by Alzheimer's; if they have/had, it also asked for how often they visit their affected relative [9].

The main objective of the survey was to determine the awareness of Alzheimer's disease, across all young adults (regardless of age, sex and other background). Other objectives were to determine whether there existed any difference in knowledge across different subgroups - between men and women, between younger and older young adults, and between those with and without family members with Alzheimer's disease.

Statistical Analysis

The same statistical analysis conducted by Chow et al. [2] was executed. Descriptive statistics were used to report the six items - 1 reflection and 5 knowledge questions - on page 3. For each participant, an overall score out of 5 was generated for the number of questions they correctly answered, with the answer key being: Alzheimer's Disease is a form of dementia - True; Alzheimer's is part of the normal aging process - False; Alzheimer's worsens over time - True; There is no cure for Alzheimer's only treatments for symptoms - True; Alzheimer's is a leading cause of death - True. Participants with scores of 4 or 5 out of 5 were interpreted to be knowledgeable about Alzheimer's disease; those with 3 were marked as having satisfactory knowledge; those scoring 1 or 2 had poor awareness about the disease.

Subgroup analyses were conducted based on ages of participants (under 20 years old, and 20 years old and older), sex (male and female), and their family's history with Alzheimer's

disease (affected and not affected). Fisher-exact tests were conducted to determine whether there was a difference in awareness between these groups. P-values less than 0.05 were deemed to be statistically significant. All analyses were conducted using the Statistical Analysis Software (SAS Version 9.4 for Windows).

OUR FINDINGS

14 individuals consented and completed the questionnaire, with their primary location of residence ranging from Taiwan to China to Dubai. 71% reserved judgement about whether they were knowledgeable or not knowledgeable about the disease, with only 21% believing that they are indeed knowledgeable. A majority (57%) of participants correctly answered that Alzheimer's is a subtype of dementia, 79% responded that Alzheimer's is not normal with respect to the aging process, 93% acknowledged that Alzheimer's worsens over time, and 93% noted that there is no cure to Alzheimer's. Only 21% of respondents correctly noted that Alzheimer's is a leading cause of death. Overall, 42% of participants were knowledgeable, while 50% and 7% had satisfactory and poor awareness, respectively (see Table 1).

Under 20 Years Old vs 20 Years Old and above

4 of the 14 participants were under 20 years old, and 10 were 20 years old and older. There were no differences in responses between the two age groups. While 56% of those 20 years old and older refused to comment about their level of awareness, 100% of those under 20 years of age withdrew their judgement ($p=0.3257$). 60% and 56% of the younger and older cohort, respectively, recognized that Alzheimer's is a subtype of dementia ($p=0.2867$). 80% and 78% of the two groups, respectively, acknowledged that Alzheimer's is not part of the normal aging process ($p=0.9999$). With respect to the question of whether there is a cure for Alzheimer's, 80% of the younger cohort and 100% of the older cohort recognized that there is no cure ($p=0.3571$). The majority of the respondents failed to recognize that Alzheimer's is a leading cause of death, with 60% and 56% falsely believing it is not ($p=0.2867$). Overall, 60% and 33% of the younger and older cohort, respectively, were deemed knowledgeable ($p=0.1608$) (see Table 2).

Males vs Females

Of the 14 respondents, 7 were male and 7 were female. 71% of males and 71% of females remained neutral about they were knowledgeable about Alzheimer's disease ($p=0.9999$). 29% and 14% of males and females, respectively, answered that Alzheimer's is a subtype of dementia ($p=0.1434$). Among the females, 100% responded that Alzheimer's is not part of the normal aging process (vs 57% for males; $p=0.1932$), 86% answered that Alzheimer's worsens over time (compared to 100% for males; $p=0.9999$), 100% acknowledged that there is no cure to Alzheimer's (vs 86% for males; $p=0.9999$), and only 29% correctly recognized that Alzheimer's is a leading cause of death (compared to 14% for

males; $p=0.9999$). There was a trend that females are more knowledgeable than males about Alzheimer's disease, with 71% deemed as knowledgeable compared to 14% among males ($p=0.1026$) (see Table 3).

Knowledgeable (4-5)	1 (14%)	5 (71%)	

Affected vs Not Affected

6 had family members who were affected by Alzheimer's disease, whereas 8 did not have a family member to their knowledge afflicted by the disease. There was no difference in self-belief and actual knowledge. 88% of those not affected and 50% of those affected did not classify themselves as knowledgeable or not unknowledgeable ($p=0.3287$). With respect to the question of whether Alzheimer's is a subtype of dementia, 50% and 63% of those affected and unaffected, respectively, acknowledged that it is a subtype ($p=0.7902$). 67% and 88% of the same cohorts, respectively, noted that Alzheimer's is not normal with respect to aging ($p=0.6923$). 100% of those unaffected noted that Alzheimer's worsens over time (compared to 83% for those affected; $p=0.4286$) and that there is no cure to Alzheimer's (compared to

83% for those affected; $p=0.4286$). 33% of those affected and 13% of those unaffected noted that Alzheimer's is a leading cause of death ($p=0.7902$). Overall, 50% of those affected and unaffected had satisfactory knowledge ($p=0.7669$) (see Table 4).

Table 4. Awareness of young adults with family members affected/not affected

Evaluation Metric	Affected (n = 6)	Not Affected (n = 8)	p-value
Self-belief of being knowledgeable			0.3287
Yes	2 (33%)	1 (13%)	
Neutral	3 (50%)	7 (88%)	
No	1 (17%)	0 (0%)	
Alzheimer's is a subtype of dementia			0.7902

Overall Score			0.7669
Poor (1-2)	1 (17%)	0 (0%)	
Satisfactory (3)	3 (50%)	4 (50%)	
Knowledgeable (4-5)	2 (33%)	4 (50%)	

DISCUSSION

21% of participants believed that they were knowledgeable with respect to Alzheimer's disease; according to the knowledge questions of the survey, 42% turned out to be aware of the disease. Given that 42% of respondents had family members affected by the disease, it seems that the young adult population of Asia is adequately aware.

The data reveals that there is not a surplus of individuals who are aware of the Alzheimer's disease. While prior studies [2-6] have yielded higher proportions of individuals with awareness as opposed to affected family members, this study shows that the proportions are just equal. This may be a result of different educational and medical systems, as well as different publicity levels of the disease, which may lead to different awareness levels.

This study was not without limitations. As with prior studies [6], the sample size of the study had good quality and quantity at times, but only lead to detection of trends rather than significant differences at other points - a large sample size would have mitigated this issue. Additionally, there exists the possibility that participants could have employed reference

resources to assist in their answers - this is unfortunately avoidable due to the medium of the survey, but was hopefully minimized by assuring participants that the quiz is an assessment of knowledge and should be answered honestly without help.

In conclusion, 42% of the population had a family member affected by Alzheimer's disease. Exactly 42% of the participants were well-aware of the disease, although only 21% of them believed so. This trend is slightly different than those determined in previous studies, and this may be a result of the different geographical region and different education/awareness levels. Follow-up studies should look into whether this different trend transcends into other regions of the globe.

ACKNOWLEDGMENT

We would like to thank all of those who participated in the questionnaire.

Chapter 240

YOUNG ADULTS AND AWARENESS OF ALZHEIMER'S DISEASE: A META-ANALYSIS

***Ronald Chow**, *BMSc(C)*, *Michael Borean*, *BMSc(C)*
and Drew Hollenberg, *BMSc(C)***

Infinitas Research Group, London, Ontario, Canada

ABSTRACT

Studies have looked the awareness level of young adults across the globe. The aim of this review was to identify existing literature and synthesize the data to observe if there are any overarching trends between young adults in various locations. A literature search was conducted in many databases, such as Ovid MEDLINE and OLDMEDLINE, Embase Classic and Embase, PsycINFO. Relevant studies were screened to determine whether it reported about awareness level of young adults with respect to Alzheimer's disease. The extracted endpoints were: self-belief levels of awareness, and actual awareness levels based on scores of knowledge questions. A total of 12 studies were identified to be included in the meta-analysis. 44% of young adults perceived themselves as knowledgeable, which is lower than the actual rate of 62% unsheathed by the literature. There exist variations between geographic regions on awareness level: American young adults were the least knowledgeable, but were more knowledgeable about certain questions (i.e., recognizing that Alzheimer's is not normal with respect to aging). However, since the review did not employ any statistical analysis, it is difficult to interpret whether the variations are significant. What is known for sure is that it seems that young adults are much more aware and knowledgeable about Alzheimer's disease than they thought they were.

INTRODUCTION

Tools have been developed for healthcare professionals to improve quality of care for dementia and Alzheimer's patients [1]. However, this is not a perfect solution. Since there is no cure for Alzheimer's disease on the horizon, another method to improve quality of life for patients would be to increase awareness of the disease amongst family members to have more conscientious caregivers [2].

Studies have looked the awareness level of young adults across the globe. For example, 75% of young adults in London, Canada, have been reported to be well-aware of the disease, but only 48% believed that they were knowledgeable [3]. The aim of this review was to identify existing literature and synthesize the data to observe if there are any overarching trends between young adults in various locations.

LITERATURE SEARCH

A literature search was conducted in databases, such as Ovid MEDLINE, OLDMEDLINE, Embase Classic, Embase and PsycINFO. Relevant studies were screened to determine whether it reported about awareness level of young adults with respect to Alzheimer's disease. The extracted endpoints were: self-belief levels of awareness, and actual awareness levels based on scores of knowledge questions. These endpoints were compiled into a table and summed to produce a weighted average for each endpoint.

SEARCH FINDINGS

A total of 12 studies [3-14] were identified to be included in the meta-analysis. Of the 12, six [3-8] were carried out in the Canadian Province of Ontario, and two more were carried out in the Provinces of Saskatchewan [9] and Quebec [10]. Another two studies [11, 12] were carried out in the States of New York and North Carolina, in the United States; two studies were conducted outside of North America, in Dublin, Ireland [13] and Asia [14].

43%, 31% and 53% of young adults in the Provinces of Ontario, Saskatchewan and Quebec, respectively, believed that they were knowledgeable about Alzheimer's disease. Across all Canadian studies, 44% acknowledged themselves as well-aware. 49% of young adults in the United States of America and 44% of those outside North America similarly recognized themselves as knowledgeable about the disease. Overall, 44% of young adults registered themselves as knowledgeable (see Table 1).

Outside North America	19 (38%)	27 (54%)	4 (8%)
TOTAL	295 (44%)	301 (45%)	72 (11%)

Young adults in the USA recognized that Alzheimer's is a subtype of dementia less frequently than those in Canada and Outside of North America (67%, vs 77% and 76%, respectively). Young adults in general, regardless of demographic region, correctly responded to the question at a rate of 76% (see Table 2).

Outside North America	38 (76%)	6 (12%)	6 (12%)
TOTAL	507 (76%)	96 (14%)	65 (10%)

With respect to the question about whether Alzheimer's is a normal aspect of aging, young adults in USA responded at a higher frequency that it is not normal – 87%. Young adults in Canada made a similar remark at 81% frequency, followed by 80% for young adults outside of North America (see Table 3).

Outside North America	8 (16%)	2 (4%)	40 (80%)
TOTAL	87 (13%)	37 (6%)	544 (81%)

Young adults answered that Alzheimer's worsens over time at a rate of 89% [11] to 100% [4, 6]. Young adults registered the correct answer at a 93% frequency, with Canadian and American young adults answering it correctly at a 93% frequency and those outside of North America registering the response 92% of the time (see Table 4).

Outside North America	45 (90%)	3 (6%)	2 (4%)
TOTAL	604 (90%)	49 (7%)	15 (2%)

Those outside of North America were least likely to accurately report that Alzheimer's is a leading cause of death, only at a frequency of 22%. Canadian young adults responded similarly at a rate of 25%, while American young adults noted it at 31%. Young adults, in general, responded to the question at 25% frequency (see Table 6).

United States of America	26 (31%)	22 (26%)	37 (44%)
Chow et al. [13]	8 (22%)	19 (53%)	9 (25%)
Viehweger et al. [14]	3 (21%)	3 (21%)	8 (57%)
Outside North America	11 (22%)	22 (44%)	17 (34%)
TOTAL	168 (25%)	233 (35%)	267 (40%)

American young adults seemed to have a lower percentage of young adults who were knowledgeable about the disease, with only 59% of young adults deemed as knowledgeable based on the study methods. Canadian young adults and those outside of North America had 62% and 68% of their populations, respectively, classified as knowledgeable. The consensus seems to be that 62% of the population is well-aware (see Table 7).

DISCUSSION

This is the first meta-analysis to look into synthesizing the published data from literature that published about awareness levels at different geographic regions around the world. This review allows for those studies with small sample sizes, whose trends were previously overlooked due to low statistical power, to be conglomerated with other studies and examine for overarching trends.

Across all 12 studies, 44% of young adults perceived themselves as knowledgeable, which is lower than the actual rate of 62% unsheathed by the literature. There exists variations between geographic regions on awareness level: American young adults were the least knowledgeable, but were more knowledgeable about certain questions (i.e., recognizing that Alzheimer's is not normal with respect to aging).

This review was not without limitations. The review did not employ any statistical analysis, which did not allow for the detection of definitive differences between different regions with respect to knowledge, answer items, and awareness level.

In conclusion, this novel meta-analysis synthesized the published data to produce conglomerate rates. While 44% of young adults recognized themselves as knowledgeable about this disease, it turned out that 62% of young adults were actually knowledgeable. It seems that young adults are much more aware and knowledgeable about Alzheimer's disease than they thought they were.

ACKNOWLEDGMENTS

We would like to thank Infinitas Research Group for all their work in the published primary research. We would also like to thank Tharani Anpalagan, Anna Rzepka and Jaclyn Viehweger in their support and assistance of the preparation of this manuscript.

Chapter 241

YOUNG ADULTS AND AWARENESS OF ALZHEIMER'S DISEASE BY AGE, SEX AND FAMILIAL TIES: A META-ANALYSIS

and Drew Hollenberg, BMSc(C)**

Infinitas Research Group, London, Ontario, Canada

ABSTRACT

A prior meta-analysis documented the overall awareness level as detailed by the studies. However, the studies included within included subgroup data, allowing for re-analysis of the data. The aim of this review was to identify existing literature and synthesize the data to observe if there are any overarching trends between young adults in various locations between certain subgroups – age, sex, and relationship to disease. Similar to the prior review, the extracted endpoints were: self-belief levels of awareness, and actual awareness levels based on scores of knowledge questions. These endpoints were compiled into a table and summed to produce a weighted average for each endpoint. The endpoints were produced for multiple pairwise disjoint events – age cohorts (under 20 years old, and 20 years old and older), gender (male, and female), and familial ties to the disease (aware of a family member affected by Alzheimer's disease, and not aware of any family members affected by the illness). 37% of the population contained within the studies had a family member affected by Alzheimer's disease. Interpreted in lieu of the prior meta-analysis that suggested that 62% of the same population was knowledgeable about the disease, it seems that the young adult population is adequately aware of the disease. Additionally, this review suggests that there may exist differences in awareness between males and females, and between those with and without family members affected by Alzheimer's disease. However, given that this meta-analysis did not employ statistical analysis, it is difficult to definitively conclude that there exists a significant difference between the subgroups.

INTRODUCTION

Past studies have revealed that healthcare professionals have developed standardized and validated tools to help improve quality of care for dementia and Alzheimer's patients, who frequently suffer undermanagement of their disease [1]. To improve quality of care even further, family members can educate themselves about the disease to be more diligent and conscientious caregivers [2].

A study conducted by Infinitas Research Group first examined into the awareness level of young adults in London, Canada, with respect to Alzheimer's disease [3]. The study determined that 75% of young adults reported to be well-aware of the disease, although only 48% of them were confident in themselves as being knowledgeable. Given that 31% of the sampled population has a family member affected by Alzheimer's disease, it seems that young adults are adequately aware.

Many similar studies were conducted [4-14], with the same aim. A prior review [15] documented the overall awareness level as detailed by the studies. However, the studies included within included subgroup data, allowing for re-analysis of the data. The aim of this review was to identify existing literature and synthesize the data to observe if there are any overarching trends between young adults in various locations between certain subgroups – age, sex, and relationship to disease.

OUR SEARCH

A literature search was conducted in many databases, such as Ovid MEDLINE and OLDMEDLINE, Embase Classic and Embase, PsycINFO. Relevant studies were screened to determine whether it reported about awareness level of young adults with respect to Alzheimer's disease.

Similar to the prior meta-analysis [15], the extracted endpoints were: self-belief levels of awareness, and actual awareness levels based on scores of knowledge questions. These endpoints were compiled into a table and summed to produce a weighted average for each endpoint. The endpoints were produced for multiple pairwise disjoint events – age cohorts (under 20 years old, and 20 years old and older), gender (male, and female), and familial ties to the disease (aware of a family member affected by Alzheimer's disease, and not aware of any family members affected by the illness).

OUTCOMES

Twelve studies were included in this meta-analysis. Eight looked into the awareness of Canadian young adults [3-10], two studied American young adults [11, 12], and another two documented the awareness level of young adults outside of North America [13, 14].

42% of under the age of 20 years old and 47% of those over the age of 20 regarded themselves as knowledgeable. Those under 20 years old and residing outside of North America had the lowest confidence level, at 35% (see Table 1). 76% of both groups recognized that Alzheimer's is a subtype of dementia (see Table 2); American young adults least commonly correctly answered the question – 68% for those under 20 years old and 66%

for those 20 years old and older. The older cohort was more likely to recognize that Alzheimer's is not normal with respect to aging, at a 88% rate compared to a 85% rate (see Table 3). The younger group more often correctly answered that Alzheimer's worsens over time (94% compared to 92%) (see Table 4), that Alzheimer's lacks a cure (92% compared to 89%) (see Table 5), and that Alzheimer's is a leading cause of death (26% compared to 24%) (see Table 6). In general, the young adults 20 years old and older seemed more knowledgeable, with 65% receiving a score of knowledgeable as opposed to 61% for the younger group (see Table 7).

Females were more likely to recognize themselves as well-aware of the disease (45% vs 41% for males) (see Table 8). Males, compared to females, failed to recognize that Alzheimer's is a subtype of disease, with a lackluster 64% rate compared to 81% rate of selecting the correct response (see Table 9). Males also were less likely to correctly note that Alzheimer's is not normal with respect to aging (77% compared to 88%) (see Table 10). Females reported that Alzheimer's worsens over time at 95%, and males similarly noted it at 89% (see Table 11). 81% of males and 94% of females acknowledged that there is no cure to Alzheimer's (see Table 12), and 21% and 26% of the same groups, respectively, answered that Alzheimer's is a leading cause of death (see Table 13). A larger proportion of females (67%) were considered knowledgeable when compared to males (50%) (see Table 14).

Young adults who have a family member afflicted by Alzheimer's disease were much more confident in their awareness of the disease, with 60% compared to 35% registering themselves as knowledgeable (see Table 15). There was a 5% difference in frequency of correctly answering that Alzheimer's is a subtype of dementia (79% for those affected, and 74% for those unaffected) (see Table 16). 87% and 86% of those affected and unaffected by the disease noted that Alzheimer's is not normal with respect to aging (see Table 17). Those with family members affected also noted that Alzheimer's worsens over time at a 96% frequency (compared to 92%) (see Table 18), that there is no cure to Alzheimer's at a 92% rate (compared to 90%) (see Table 19), and that Alzheimer's is a leading cause of death at 30% frequency (compared to 22%) (see Table 20). Overall, those with family members affected by the disease seem to be more knowledgeable, with 65% compared to 61% receiving a score deeming them knowledgeable (see Table 21).

DISCUSSION

This review is a follow-up meta-analysis one previously conducted [15]. 37% of the population contained within the studies had a family member affected by Alzheimer's disease. Interpreted in lieu of the prior meta-analysis that suggested that 62% of the same

population was knowledgeable about the disease, it seems that the young adult population is adequately aware of the disease.

According to subgroup analyses, it seems that females are more knowledgeable than males and those with family members affected compared to those without family members affected, were more well-aware of the disease. Both of these observations may be a result of more diligence and personal care about the disease. This review was not without limitations. The review did not employ statistical analyses, and hence the differences observed could not be determined to be statistical differences.

This secondary meta-analysis suggests that young adults are well-aware of Alzheimer's disease. Additionally, it suggests that there may exist differences in awareness between males and females, and between those with and without family members affected by Alzheimer's disease. However, given that this meta-analysis did not employ statistical analysis, it is difficult to definitively conclude that there exists a significant difference between the subgroups.

ACKNOWLEDGMENTS

We would like to thank Infinitas Research Group for all their work in the published primary research. We would also like to thank Tharani Anpalagan, Anna Rzepka and Jaclyn Viehweger in their support and assistance of the preparation of this manuscript.

Chapter 242

ASSOCIATIONS WITH OBESITY IN SUB-SAHARAN AFRICA

Yackoob K. Seedat*

Emeritus Professor of Medicine, Department of Internal Medicine,
University of KwaZulu-Natal, Durban, South Africa

HYPERTENSION

There is a strong association between obesity, hypertension, and obesity. About three-quarters of adult type II diabetics and some two-thirds of hypertensives are overweight (Modan et al., 1985). Obesity as defined as body weight 20% or more above average or standard weight appears to be the link between diabetes and essential hypertension in a large majority of cases. However about 15.0% of the study's hypertensive group were free of the other two conditions, and some 4.7% of the general population presented all three of them. Thus it can be estimated that nearly 1 out of 10 of those in middle age and having a Westernised lifestyle are heavier than normal weight, more or less glucose intolerant, and have systolic or diastolic hypertension (Ferranini & De Fronzo, 1989).

Hypertension is common in patients with diabetes. Studies within populations have shown that hypertension occurs more frequently in patients with diabetes than in nondiabetic individuals (Kannel & McGee, 1979). And it is more common for hypertensive patients to become diabetic than for diabetic patients to become hypertensive. Hypertension associated with diabetes may be of three types: a) systolic hypertension secondary to atherosclerosis, and about 2-5 times as prevalent in diabetes as in nonmatched nondiabetics; b) renal hypertension secondary to diabetic nephropathy; and c) essential hypertension.

HYPERINSULINAEMIA

Plasma insulin levels are consistently increased in obese subjects (Salans, 1981). Likewise, patients with impaired glucose tolerance usually are hyperinsulinaemic even if their body weight is normal. Thus it is possible that patients with impaired glucose tolerance usually are hyperinsulinaemic even if their body weight is normal (De Fronzo & Ferranini, 1982). Thus it is possible that hyperinsulinaemia could be one link between diabetes, obesity, and hypertension. The association between hyperinsulinism and hypertension was noted in a large Israeli Jewish population characterised by a high prevalence of glucose intolerance and diabetes. The patients were stratified for age and body mass. It was found that the prevalence of hypertension as well as the actual BP rose from normal to overt diabetes. They concluded that hypertension per se is associated with hyperinsulinaemia, and there is common ground for the cluster of diabetes, obesity, and essential hypertension (Modan et al., 1985).

INSULIN RESISTANCE

Insulin resistance is reduced or impaired response of target tissues to insulin stimulation (Salans, 1981; Ferranini & De Fronzo, 1989). Insulin resistance occurs in 25% of normal people (De Fronzo & Ferranini, 1982). The impact of insulin on glucose may be unrelated to impacts of insulin on carbohydrate, fat, protein, or electrolyte metabolism. Insulin resistance occurs in obesity and in noninsulin-dependent diabetes. The actions of insulin can be studied with the insulin clamp technique.

AETIOLOGY OF THE INSULIN-RESISTANT STATE

Several causes may be associated with the aetiology of the insulin-resistant state, including genetics, hyperinsulinaemia, increased level of androgen with central obesity, elevated levels of free fatty acid, ageing, physical inactivity, diabetes and/or obesity, pregnancy, oral contraceptive pill, glucocorticoids, growth hormone, alcohol, and smoking (Lundgren et al., 1988; Pollare, 1989)..

ROLE OF INSULIN IN CAUSING HYPERTENSION

Insulin can raise BP by increased sodium retention (De Fronzo, 1981), or insulin can stimulate the activity of the sympathetic nervous system. An increased concentration of noradrenaline leads to increase in heart rate, vasoconstriction, sodium retention, and elevated BP (Rowe et al., 1981). Insulin also affects the transport of positive ions across the cell membrane. This affects sodium, potassium, calcium, and magnesium. An altered salt concentration in the endothelial cell can reduce the contractility of skeletal and heart muscle (James et al., 1985; Hilton, 1986). In theory, elevated insulin levels can increase the contraction of the vascular wall, resulting in an elevated BP.

OBESITY—THE HARMFUL MALE TYPE

Abdominal obesity, i.e., the male type of obesity, brings increased risk of cardiovascular disease, while female obesity of the hip and thigh is not associated with cardiovascular disease. Abdominal obesity is associated with the following features: a) higher fasting insulin levels, b) reduced glucose tolerance and an increased risk of hypertension and diabetes, c) reduced insulin sensitivity, d) blood lipid abnormalities, e) higher levels of free fatty acid, because adipose tissue is more sensitive to catecholamine lipolysis, and f) an increased number of fast-twitch, white muscle fibres in the thigh muscle. Abdominal obesity is associated with increased incidence of coronary heart disease (CHD) before ages 60-65 years.

TREATMENT

Treatment for obesity should be by weight reduction, a diet consisting of less fat and more fibre, and an increase in physical activity. Smokers should receive advice on how to stop. The entire cardiovascular profile can be improved with this regimen. Pharmacological agents that have no metabolic side effects should be considered. In the syndrome of hypertension, obesity, and diabetes, one should consider hypotensive agents that lower BP and enhance insulin sensitivity. In this setting, drugs should be considered that lower BP and improve insulin sensitivity, like angiotensin converting enzyme inhibitors. Of patients in one study who developed diabetes, 98% were treated with diuretics and/or beta blocking agents (Pollare et al., 1989).

LIFESTYLE

Two important low-cost measures are, first, a reduction of dietary salt and increased potassium intake, and second, a greater awareness of the serious implications of obesity. Increased exercise, decreased obesity, and cessation of smoking are all important in Blacks and whites in control of hypertension. Financial and cultural barriers constrain implementation of the DASH high-fruit, high-vegetable, low-salt diet which is very effective in U.S. Blacks. In Africa, one hypothesis is that the rural diet is relatively protective but is abandoned with urban exposure that entails less carbohydrate and higher fat intake. In West Africa, sodium restriction is feasible as a solitary measure, but to achieve general adoption, it requires persuasion at a governmental level and multiple messages from various sources, including rural clinics and television (Cappuccio et al., 2004). The major problem is how to get lifestyle messages across and how to implement them.

HYPERTENSION IN SUB-SAHARAN AFRICAN POPULATIONS

Hypertension in sub-Saharan African populations is a widespread problem of immense economic importance because of its high prevalence in urban areas, its frequent

underdiagnosis, and the severity of its complications. Mass migration from rural to periurban and urban areas probably accounts at least in part for the high incidence of hypertension in urban black Africans. In semirural areas, inroads in lifestyle changes associated with “civilisation” may explain the apparently rising prevalence of hypertension. Significant segments of the African populations are still afflicted by severe poverty, famine, and civil strife, making the prevalence of hypertension difficult to determine. Black South Africans have a stroke rate twice as high as that of whites. Two lifestyle changes that are feasible and can help stem the hypertension epidemic in Africa are a decrease salt intake and a decrease in obesity, especially in women (Opie & Seedat, 2005).

Exact data are difficult to obtain in South African surveys. In 1983 our age-adjusted prevalence study (Seedat, 1983) of the adult population of Durban (World Health Organisation criteria ≥ 160 mm Hg) showed that hypertension was highest in urban Blacks of the Zulu tribe (25%), followed by whites (17%), ethnic Indians (14%), and lowest in rural Blacks (9%). The first Demographic and Health Survey in South Africa was conducted in 1998 in a random sample of 13,802 subjects aged 15 years or older, of whom 76% were Black, 13% of mixed ancestry, 8% white, and 3% Indian/Asiatic. The age-adjusted incidence of hypertension, namely BP $\geq 140/90$ mm Hg on medication, measured automatically, for the predominantly Black South African population was 21% (equal rates among males and females). For those > 65 years of age, 50% to 60% were hypertensive (Steyn et al., 1998), a slightly higher rate than those of a similar age group in semi-urban West Africa (Cappuccio et al., 2004).

Increasing obesity has been associated with increasing BP levels in West African and U.S. Blacks. In the South African Demographic and Health Survey of 1998, the incidence of obesity (body mass index was about 30% in females and 8% in males) was as high as 40%-49% in females and 13% in men (Steyn et al., 1998). Abdominal obesity was particularly common in females. The more urbanised these communities were, the higher the rate of obesity and the less prudent their diets became. It is probable that the lower male prevalence relates in part to the higher rate of heavy manual labour.

DIABETES MELLITUS IN SOUTH AFRICAN INDIANS

A dramatic increase in the prevalence of type 2 diabetes is observed in many parts of the Indian diaspora, which includes the United Kingdom, Mauritius, and Fiji. Whilst there are marked cultural and social differences within the Indian racial group, Indians have the unenviable distinction of achieving a high death rate from CHD. Much of this additional high risk of type 2 diabetes may be due to the increased risk of type 2 diabetes (four times that of Europeans), which develops in Indians about 10 years earlier than in South African whites (Seedat, 1999; Seedat, 2005).

In a community study (World Health Organization, 1985) to determine the prevalence and known risk factors for CHD of 778 subjects in the metropolitan area of Durban, diabetes mellitus was present in 15.8% (age and sex adjusted for 12.4% of the total sample).

INCIDENCE OF INSULIN RESISTANCE

Insulin resistance consists of glucose intolerance, hyperinsulinaemia, hypertension, dyslipidaemia, low plasma HDL cholesterol, and high triglyceride (Reaven, 1988).²¹ We have found that important factors denoting insulin resistance were associated with hypertension; hypercholesterolaemia, low plasma HDL cholesterol, truncal obesity, diabetes, and hypertriglyceridaemia were clustered in Indians in Durban (Seedat et al., 1991).²² The Indian population has been shown to have high plasma insulin levels with insulin glucose tolerance. Young Indian medical students develop metabolic risk factors for CHD at an early age, compared with young Black medical students (Morar et al., 1998). It has been suggested that insulin resistance in the South Asians of London, U.K., leads to a high incidence of CHD (McKeigue et al., 1991). We consider that this interesting concept could explain the high incidence of CHD in migrant Indians throughout the world.

Our study shows that diabetes mellitus is common in the South African Indian population. The aetiology may consist of insulin resistance, abnormal dietary patterns consisting of low energy intake, high intake of polyunsaturated fatty acids, low fibre intake, and physical inactivity (Wolmarans et al., 1999). Because of the higher risk of cardiovascular disease with diabetes, Indian patients should be treated, with lower thresholds for intervention, for hypertension, dyslipidaemia, and hyperglycaemia compared to white patients.

CORONARY HEART DISEASE IN DURBAN BLACKS—LINKS IN URBAN RACIAL GROUPS

CHD is still relatively uncommon in the Black population of South Africa. We embarked on a study to determine the prevalence of risk factors leading to CHD in the Black population of Durban. A total of 458 patients attending a hospital dental clinic were studied. The prevalence of CHD was 2.4%. The prevalence of risk factors were as follows: hypertension (TSP $\geq$ 140 mm Hg systolic and/or $\geq$ 90 mm Hg diastolic), 28.0% (31.9% for males, 25.4% for females); protective levels of high-density lipoprotein / total cholesterol $\geq$ 20.0%, 81.3%; diabetes mellitus, 4.9% for males, 2.9% for females; smoking $\geq$ 10 cigarettes per day, 28.1% for males, 3.4% for females; obesity, 3.7% for males, 22.6% for females. We found the Minnesota Coding system for electrocardiographic changes and the Rose questionnaire to be unreliable for eliciting CHD in Blacks. Hypercholesterolaemia was found to be less common, and this may explain the low incidence of CHD in Blacks. Epidemics of CHD seen in Indian, Coloured, and white South Africans can still be prevented in the Black population, but preventive measures must be initiated rapidly (Seedat et al., 1992).

Metabolic syndrome is a clustering of interrelated risk factors namely, dysglycemia, increased blood pressure, elevated triglyceride levels, low high-density lipoprotein levels, and obesity, particularly central obesity. This syndrome has been known for decades now and has been observed with the rising prevalence of obesity and the modern-day sedentary lifestyle. Insulin resistance linked with central, essentially visceral, adiposity remains to be postulated as its underlying pathogenetic mechanism. It is significantly associated with increased risk for the development of cardiovascular disease, 2x and higher, and for type 2 diabetes mellitus, 5x and higher, in individuals fulfilling its diagnostic criteria (Alberti et al., 2009).

Defining the diagnostic criteria of the metabolic syndrome (MS) has been a major task of several health organizations representing major stakeholders in the fields of cardiovascular and metabolic diseases. Varying sets of diagnostic criteria have been recommended previously by different organizations such as the World Health Organization (WHO) in 1998, the European Group for the Study of Insulin Resistance (EGIR) in 1999, the National Cholesterol Education Program's Adult Treatment Panel III (ATP III) in 2001, the American

* Corresponding Author's Email: gjasul@yahoo.com.

Association of Clinical Endocrinologists (AACE) in 2003, the International Diabetes Federation (IDF) in 2005 and the American Heart Association (AHA) and National Heart, Lung and Blood Institute (NHLBI) also in 2005 (Sperling et al., 2015). The harmonized definition of the metabolic syndrome (summarized in Table 1) was issued in 2009 from the joint scientific statement of the International Diabetes Federation Task Force on Epidemiology and Prevention (IDF), National Heart, Lung and Blood Institute (NHLBI), American Heart Association (AHA), World Heart Federation (WHF), International Atherosclerosis Society (IAS) and the International Association for the Study of Obesity (IASO) (Alberti et al., 2009, Sperling et al., 2015).

Table 1. Criteria for the clinical diagnosis of metabolic syndrome (MS)

Measure	Categorical cut points
Elevated waist circumference	Population or country-specific definitions
Elevated triglycerides (drug treatment for increased triglycerides is an alternate indicator)	≥ 150 mg/dl
Reduced HDL-cholesterol (drug treatment for low HDL is an alternate indicator)	Males: < 40 mg/dl Females: < 50 mg/dl
Elevated blood pressure (antihypertensive drug treatment for elevated BP is an alternate indicator)	Systolic BP ≥ 130 mm Hg and/or Diastolic BP ≥ 85 mm Hg
Elevated fasting glucose (drug treatment for elevated blood sugar is an alternate indicator)	FPG ≥ 100 mg/dl

NOTE: The use of ethnic-specific cut-offs for waist circumference is recommended and thus applied. The Asian cut-offs, ≥ 90 cm for males and ≥ 80 cm for females are used for the Philippine data from 2008. The presence of 3 of 5 criteria in each individual fulfills the diagnosis of metabolic syndrome.

Metabolic syndrome evolved both as a public health and a clinical problem largely because obesity is at the core of this clustering that carries a very high cardiometabolic risk. The contribution of obesity is critical thus eliciting further examination of the nature of obesity, the phenotypic profile, including the age, gender, ethnicity of the individuals with this syndrome. It becomes evident that individual characteristics define the cardiometabolic profile of different populations that in turn define their cardiometabolic risk. Better measures of obesity, particularly central obesity, are necessary and hence, waist circumference as a simple and cost-effective measure of central obesity is a critical criterion in diagnosing metabolic syndrome. The important ethnic-specific and gender-specific cut-offs for waist circumference reflects the epidemiologic evidence of the differences in cardiometabolic risk between individuals and between populations (Blucher, 2014, Seo and Rhee, 2014).

Given this general background on metabolic syndrome, the current discussion will now focus on the epidemiology of this syndrome among Filipino adults, the similarities in the cardiometabolic profile of other Asian and Asia-Pacific populations vis-à-vis their Caucasian and non-Asian counterparts. The increasing prevalence of overweight and obesity is apparently driving the global diabetes epidemic and the consequent rise in cardiovascular and related diseases. This chain of events in the face of nutrition and lifestyle transition in amidst Westernization in developing countries is further magnified in the Asia-Pacific region where the majority of people with new-onset type 2 diabetes reside. Approximately half of the 422 million adults with diabetes in 2014 are from the Southeast Asia and Western Pacific regions

(WHO 2016). The magnitude of the obesity problem, while clearly on the rise as well in these regions, is not proportional to the staggering diabetes burden in these regions.

Table 2. Survey data used for Figure 1

	Survey year	Prevalence of overweight adults (%) ^a	Prevalence of obese adults (%) ^a	Prevalence of diabetes (%)
USA	1999-2000 ^a	34.0	10.0	
	1999-2000 ^a			8.2

Source: From Yoon, Lee, et al., Lancet 2006; 368: 1684.

Figure 1. International comparison of prevalence of adult obesity and diabetes. (A) Proportion of overweight and obese adults, (B) Prevalence of diabetes.

In an international comparison in 2003, with 34% and 30% of Americans being overweight and obese, respectively, the US national prevalence of diabetes was 8.2%. The overweight and obese Asians, on the other hand, ranged then from 10 to 28% and 2 to 6.8%, respectively in 7 countries (India, Philippines, Taiwan, Hong Kong, China, Singapore, Korea, and Thailand) and yet the average diabetes prevalence in these countries already ranged from 5 to 12% (Figure 1 and Table 2) (Yoon, Lee, et al., 2006). Diabetes, an important component of the metabolic syndrome, appears to develop among Asians, including Filipinos, at lower levels of obesity. It thus becomes important to examine closely the distinguishing characteristics of Filipinos, and Asians for that matter, with metabolic syndrome.

THE PHILIPPINE DATA ON THE METABOLIC SYNDROME

In the Philippines, the national nutrition survey (NNS) provides critical data on food intake, nutrition and health status of Filipinos as mandated by Executive Order 352 guiding policy and decision-making in both the government and private sectors. Since the first survey in 1978, this statistical activity has been done regularly by the Food and Nutrition Research Institute (FNRI) of the Department of Science and Technology (DOST). The NNS has evolved in 1998 during the 5th NNS to include the clinical component in collaboration with the Department of Health and various health agencies and groups including medical specialty organizations. The NNS has been conducted every 5 years throughout the 17 regions of the Philippines covering the National Capital Region (NCR) and 80 provinces. In the 8th NNS in 2013, out of the 97.7 million Filipinos, 45,047 households with 172, 323 persons were used for the multi-staged stratified sampling design. The 9th NNS will be undertaken this year (2018). The NNS is clearly a veritable source of health information including prevalence and trends of leading health problems including non-communicable diseases in the country. The Philippine data on metabolic syndrome under discussion are derived from various reports, published papers and unpublished data from the NNS. (FNRI-DOST reports/pdf files, www.fnri.dost.gov.ph/nutrition-statistic). A few published articles outside the NNS have been included to elucidate the problem of metabolic syndrome in the Philippines.

From the 5th NNS (1998), analysis of data from 4541 Filipino adults aged 20 years and over showed the proportion of subjects with co-morbid factors increased with high fasting blood sugar (FBS), except for high cholesterol. Having high body mass index ($BMI \geq 25$), high waist-hip ratio ($WHR \geq 1.0$ in males, ≥ 0.85 in females) and high waist circumference ($WC \geq 102$ cm in males, ≥ 88 cm in females) in combination was associated with highest prevalence of high FBS in males (35.8%) and in females (14.5%) and with highest prevalence of hypertension in males (66.5%). Among females, the highest prevalence rate of hypertension (37.95) was seen among those with high FBS. This study indicated that waist circumference, with the higher cut-offs used, was the best predictor of metabolic risks, particularly of diabetes mellitus (Tanchoco et al., 2003).

Prevalence of metabolic syndrome among the same 4541 Filipino adults from the 5th NNS was determined using the NCEP and the IAS criteria in another study. For the IAS criteria, the Asian cut-offs for waist circumference, >90 cm in males and >80 cm in females, were used. Based on the NCEP criteria, the prevalence of metabolic syndrome was 14.2% and when stratified according to age, 6.6% (ages 20-39 years), 17.7% (ages 40-59 years), and

18.3% (ages 60 years and older). Using the IAS criteria, the prevalence of metabolic syndrome was 19.3% and with age stratification, 10.0%, 23.6%, and 24.1%, respectively. The study concluded that metabolic syndrome was common in this population and increased in prevalence with age. It was also noted that using NCEP criteria, instead of the IAS criteria, underestimated the prevalence of metabolic syndrome (Punzalan et al., 2004).

The 6th NNS, also called the National Nutrition and Health Survey (NNHeS) 2003-2004, also integrated the clinical component similar to the 5th NNS but also determined, for the first time, the national prevalence of 24 diseases and 11 risk factors. Using 3 sets of definitions/criteria of the metabolic syndrome, namely, NCEP/ATP III (2001), IDF (2005) and NCEP/ATP III-AHA/NHLBI (2005), the prevalence of metabolic syndrome in the adult Filipinos aged 20 years and older was found to be 11.9%, 14.5%, and 18.6%, respectively. Low levels of high-density lipoprotein cholesterol (HDL-C), mean level of 41.3 mg/dL, were seen in 60.2% of men and 80.9% of women, making it the most common component of the syndrome in the population (70.2%), similarly observed in the previous 5th NNS with prevalence of 84%. The prevalence rates of the other MS components were as follows: blood pressure $\geq 130/\geq 85$, 33.3%, abdominal obesity (WC ≥ 90 cm, male, ≥ 80 female), 26.1%, triglycerides ≥ 150 mg/dL, 20.6% and fasting blood sugar ≥ 100 mg/dL, 7.1%. Age-adjusted odds ratios showed that MS, by all 3 criteria, predisposed an individual to diabetes mellitus and stroke while MS using the IDF definition predisposed an individual to myocardial infarction (Morales et al., 2008).

In the analysis of data from the 7th NNS/ NNHeS 2008, the prevalence rate of MS utilizing the harmonized definition (Table 3) was 27.4%, significantly higher than the reported 18.6% in 2003. The prevalence rates of the individual components of MS similarly showed significant increases as follow: low HDL-C, 80.3%, abnormal BP, 39.3%, abdominal obesity, 29.8%, increased triglycerides, 30.1%, and elevated FBS, 12.2%. Both age and gender-related differences continued to be observed as in the previous NNS. Age-related increases in MS peaked in the age groups 50-59 years and 60-69 years, remaining high after age 70 years. Females had more abdominal obesity and lower HDL-C while men had higher BP and higher triglycerides (Table 4) (Jasul, unpublished data, 2008).

Table 3. Prevalence of metabolic syndrome among Filipino adults aged 20 years and above, based on the harmonized definition of the IDF, NHLBI, AHA, WHF, IAS and IASO 2009: NNHeS 2008

Age (years)	Males % (SE)	Females% (SE)	Both sexes % (SE)
20 - 29	12.3 (1.27)	8.4 (1.14)	10.4 (0.86)
30 - 39	26.7 (1.79)	20.1 (1.61)	23.3 (1.22)
40 - 49	31.7 (1.97)	31.5 (1.80)	31.6 (1.40)
50 - 59	38.9 (2.42)	45.6 (2.20)	42.7 (1.74)
60 - 69	28.3 (2.87)	46.8 (2.85)	38.7 (2.13)
≥ 70	15.8 (3.13)	38.3 (3.30)	29.3 (2.40)
All	25.8 (0.87)	28.9 (0.92)	27.4 (0.67)

More rigorous analysis of the data from the 7215 Filipino adults from the 7th NNS/NNHeS 2008 concluded that the prevalence rates of measured variables, particularly the components of MS and the risk factors for atherosclerosis, were higher compared with values obtained in 2003. Among adult Filipinos aged 20 years or older, the true prevalence of

hypertension was 20.6% and the prevalence of diabetes was 3.9% based on fasting blood glucose (FBG), 5.2% by FBG and history, and 6.2% with 2-hour post-load plasma glucose was determined. Obesity, defined as BMI ≥ 30 , was seen in 4.9% but obesity defined by abnormal waist-hip ratio (WHR) of 1.0 or higher in men and 0.85 in women, was seen in 10.2% and in 65.6%, respectively (Sy et al., 2012).

Table 4. Prevalence of the individual components of metabolic syndrome (MS) among Filipino adults aged 20 years and above, by sex

MS Component	Male % (SE)	Female % (SE)	Total % (SE)
Waist circumference Male ≥ 90 cm, Female ≥ 80 cm	17.8 (0.77)	41.0 (0.97)	29.8 (0.72)
Triglycerides ≥ 150 mg/dl	37.9 (0.95)	23.2 (0.80)	30.1 (0.67)
HDL, Males < 40 mg/dl, Females < 50 mg/dl	71.6 (0.90)	88.1 (0.71)	80.3 (0.62)
Blood Pressure, $\geq 130/\geq 85$ mm Hg	44.4 (0.98)	35.0 (0.88)	39.3 (0.70)
Fasting Blood Sugar, ≥ 100 mg/dl	11.9 (0.47)	11.6 (0.65)	12.2 (0.62)

Table 5. Prevalence of blood glucose abnormalities among Filipino adults aged 20 years and above: NNHeS 2008

Glucose abnormalities	Male	Female	Total
Impaired Fasting Glucose (IFG) (FBG >100 and <125 mg/dl) (%)	7.9	6.7	7.2
Impaired Glucose Tolerance (IGT) (2-hr PPBG >140 and <199 mg/dl) (%)	6.7	7.3	7.0
Combined IFG/IGT (%)	0.4	0.6	0.5
Diabetes Mellitus, DM (FPG ≥ 126 and 2-hr PPBG ≥ 200 mg/dl)(%)	7.0	7.4	7.2

Patterns of glucose abnormalities were analyzed in a sub-study of the 7th NNS/NNHeS 2008 to address the contrasting data on prevalence and incidence rates reported from studies outside the NNS. Using FBS, 2-hour post-load glucose and DM questionnaire, the true diabetes prevalence was 7.2% and the prevalence of pre-diabetes was summed at 10.2%, with impaired fasting glucose (IFG), 2.7%, impaired glucose tolerance (IGT), 7.0% and both IFG/IGT, 0.5% (Table 5). Differences in the prevalence rates of diabetes between urban and rural populations were significant at 8.3% versus 5.8%, respectively (Jimeno et al., 2015).

From the results of the 8th NNS/NNHeS 2013, the burden of non-communicable diseases (NCDs) was reported and summarized as prevalence rates of selected risk factors. NCDs accounted for two-thirds (67%) of total deaths in the country in 2012. Obesity (BMI ≥ 30) was seen in 6.8% (males, 5.2%, females, 8.3%), with higher rates in urban areas (10.1%, National Capital Region (NCR)) than rural areas (around 4% in Ilocos Region, Cagayan Valley, Western Visayas, Autonomous Region in Muslim Mindanao (ARMM)). Combining overweight and obesity (BMI ≥ 25) totaled 31.1% of adult population (males, 27.6%, females, 34.4%), simply put, three out of ten Filipinos were overweight or obese. Central or android obesity, based on high waist circumference (males, ≥ 102 cm, females, ≥ 88 cm), was seen in 3.8% of males and 23.1% of females and based on high waist-to-hip ratio (WHR) (males ≥ 1.0 , females ≥ 0.85), was seen in 8% of males and 63.2% of females. Hypertension (SBP ≥ 140 , DBP ≥ 90) was present in 22.3% of the adult population (males, 25.1%, females,

19.9%) while diabetes (fasting blood sugar (FBG) ≥ 126 mg/dl) was seen in 5.4% (males, 5.6%, females, 5.3%).

Abnormal cholesterol levels were reported as follows: total cholesterol (TC borderline 200-239 mg/dl to high ≥ 240 mg/dl), 46.9% (males, 41.5%, females, 51.4%), LDL cholesterol (LDL-C borderline 130-159 mg/dl to high ≥ 160 mg/dl), 47.2% (males, 40%, females, 53.6%) and triglycerides (TG borderline 150-199 mg/dl, high 200-399 mg/dl to very high ≥ 400 mg/dl), 38.6% (males, 46.4%, females, 31.8%). Low HDL cholesterol (HDL-C males, <40 mg/dl, females, <50 mg/dl) was seen in 71.3% (males, 63.2%, females, 78.2%). Insufficient physical activity (not meeting 3 or more days of vigorous-intensity activity of at least 20 minutes per day or 5 or more days of moderate-intensity activity or walking of at least 30 minutes per day) was seen in 45.2% (males, 36.7%, females, 52.7%) (FNRI DOST, 2013).

Prevalence of MS has not been reported from the 8th NNS/NNHeS 2013 data but clearly, the prevalence rates of the MS components remained significantly high. The trends in the prevalence rates of these important risk factors reflect continuing rise from 1993 (4th NNS) to 2013 (8th NNS). The accompanying figures (Figures 2-5) illustrate these alarming trends that point to unabated increasing cardiometabolic risk in the general adult Filipino population. While the prevalence of chronic energy deficiency has been slowly decreasing, the prevalence of overweight and obesity has almost doubled (Figure 2). The data on the pediatric age groups also show increasing trend but to a much lesser degree. Overweight in children below ten years of age was seen in around 2% and among adolescents, less than 5%. Central obesity has been similarly increasing and more markedly among females (Figure 3). Hypertension prevalence has been relatively steady in the 21-25% range (Figure 4) but the trends in high fasting glucose has been steadily increasing (Figure 5) (FNRI DOST 2013). The measures of glucose abnormality have varied in the different NNS and estimation of the true prevalence of diabetes mellitus may be limited by this variation, as addressed by Jimeno et al., (2015).

Figure 2. Prevalence of malnourished adults, ≥ 20 years old, Philippines, 1993-2013.

Differences in the cut-offs in the measured variables are common in published literature on obesity and metabolic syndrome. Determination of the cut-offs for BMI, WC and WHR that will help define levels of risk of co-morbidities was undertaken using data from the 6th

NNS/NNHeS 2003. This sub analysis from the 2003 results emphasized that with increasing body fatness, there is an increasing risk of related co-morbidities among adult Filipinos. The tentative cut-offs associated with risk of co-morbidities were BMI of 23 for overweight and 27 for obesity, WC of 90 cm for males and 85 cm for women and WHR of 1.0 for males and 0.95 for females. These tentative cut-offs were closer to the recommended cut-offs for Asia-Pacific islanders and Asians from the International Obesity Task Force (AP/IOTF) and were considerably lower than the WHO cut-offs (Florentino and Duante, unpublished data, 2004).

Figure 3. Trends in high waist circumference and high waist hip ratio prevalence among adults, 20 years old and over, Philippines, 1998-2013.

Similar analysis was done using the 7th NNS/NNHeS 2008 results and concluded that the odds of developing 2 or more risk factors among adult Filipinos were noted even at a much lower BMI (18 kg/m²) in both males and females. The tentative cut-offs from the 2008 data were BMI of 22.5 for overweight and 27 for obesity, WC of 78 cm for both males and females and WHR of ≥ 0.92 for males and ≥ 0.88 for females. These cut-offs were almost similar to the 2003 tentative cut-offs of the AP/IOTF (Duante, unpublished data, 2008).

Several studies independent of the NNS/NNHeS revealed similar findings of a very different profile of MS in Filipinos compared to Caucasians/non-Asians. In the Philippine cohort of the LIFECARE longitudinal study in Asia, 3,702 Filipinos aged 20 to 50 years old from Metro Manila and four nearby provinces were recruited. Prevalence of MS was 19.7%, based on the IDF criteria and 25.6%, based on the modified NCEP (mNCEP) or harmonized criteria (Table 1). The IDF criteria required the presence of abdominal obesity plus any 2 of the other risk factors while the mNCEP defined it as the presence of any 3 or more of the risk factors. This basic difference was reflected in higher MS prevalence in women by IDF, higher MS prevalence in men by mNCEP, with IDF missing 40% of men and 10% women identified as having MS by mNCEP. More males were categorized as having MS by mNCEP despite relatively normal waist circumference (mean WC 80.6 cm). MS was associated with increasing age, urban residence and employed status (Sy et al., 2014).

Figure 4. Trends in the prevalence of hypertension among adults ≥ 20 years old in the Philippines: 1993, 1998, 2003, 2008 and 2013.

Figure 5. Trends in the prevalence of high fasting blood glucose among adults ≥ 20 years old, Philippines: 1998, 2003, 2008 and 2013.

In the Cebu Longitudinal Health and Nutrition Survey (CLHNS), the community-based survey followed a cohort of infants born in 1983 to 1984 with surveys immediately after birth, bimonthly for two years, in 1991, 1994-5, 1998-99, 2002, and 2005. In 2005, fasting blood were drawn for CVD biomarkers and genetics and 1,621 individuals aged 20-21 years (889 men and 732 women) were included in the cluster analysis using biomarkers. The study identified 5 distinct sex-specific clusters: 1) healthy/high HDL (with the addition of high LDL-C in women), 2) healthy/low blood pressure, 3) high blood pressure, 4) insulin resistant/high triglycerides, and 5) high C-reactive protein. Low HDL-C was the most prevalent risk factor at 65%. Men had higher prevalence of elevated triglycerides and

hypertension while women had higher prevalence of low HDL-C, elevated LDL-C and elevated HOMA-IR. Adiposity was most strongly associated with insulin-resistant/high triglyceride cluster. In this young (aged 20-21 years) and lean population (mean BMI 20-21, mean WC 72 cm (men), 68, (women), with 18% prevalence of overweight) with no significant clinical disease, cluster analysis identified patterns of cardiometabolic risk factors. Diet and environmental factors also influenced the predicted clustering of risk factors. The importance of screening both lean and overweight individuals for cardiometabolic risk was thus emphasized in such populations where the cardiometabolic risk is elevated even at lower BMI (Zubair et al., 2014).

In a rural community-based cross-sectional observational study in San Juan, Batangas, optimal cut-offs for BMI, WC and WHR for risk for cardiometabolic diseases were determined among 332 individuals, mean age of 48.4 years and 72% of whom were women. The optimal cut-offs for males and females were BMI of 24 and 23 kg/m², WC of 84 and 77 cm and WHR of 0.91 and 0.85, respectively. Similar to the analyses by Florentino and Duante and by Duante, lower indices of overweight and obesity, were associated with cardiometabolic diseases among Filipino adults in this rural community (Pagsisihan et al., 2016).

Table 6. Presence of metabolic syndrome in relation to different BMI categories and gender

BMI Category	Metabolic Syndrome		
	Male n (%)	Female n (%)	Total with Metabolic Syndrome n (%)
Normal (18.5-22.9 kg/m ²)	13 (21)	48 (33.3)	61 (29.6)
Overweight (23-24.9 kg/m ²)	41 (37.3)	59 (40.1)	100 (38.9)
Pre-obese (25-29.9 kg/m ²)	159 (63.5)	130 (53.1)	289 (58.9)
Obese (≥ 30 kg/m ²)	135 (64.6)	112 (69.9)	247 (62.4)
Overall			697 (51.0)

In a retrospective study of 1367 patient seen at the wellness center and the weight management center of a Philippine tertiary hospital, the prevalence of metabolic syndrome, defined by the mNCEP/harmonized criteria, and its individual components was determined across the different BMI categories. While the study population (mean age 53 years, mean BMI of 28 kg/m², and mean WC of 96.8 cm) did not reflect the general Filipino population, the finding of high prevalence of MS even in individuals with normal BMI (Table 6) suggests that cardiometabolic abnormalities are present even at lower and normal BMI levels (Mata and Jasul, 2017).

THE ASIAN DATA ON THE METABOLIC SYNDROME

In developing countries, the prevalence of obesity and metabolic syndrome is rapidly rising with the main causes all related to economic progress, namely, urbanization, nutrition transition and physical inactivity. This public health problem carries enormous burden of increased morbidity and mortality due to type 2 diabetes mellitus and cardiovascular disease and consequent effects on health expenditures and economic productivity. Nutrition transitioning led to a decrease in the undernourished population and an increase in the over

nourished population. This development is mirrored in the Philippines as described in the previous section of this discussion. Since the 1980s, obesity rates have increased three-fold or more in the Middle East, the Pacific Islands, Australasia, and China. Compiled data from developing countries on obesity, defined using varying BMI and WC cut-offs, showed rates as low as 2.9% to as high as 68%. Differences were evident based on gender, urban versus rural residence, educational attainment, and socioeconomic status, among others. Reported rates of metabolic syndrome using different definitions ranged from 6.5% to 46.5% in developing countries (Misra and Khurana, 2008).

Surveys from East Asian and Southeast Asian populations consistently showed increase in the prevalence of metabolic abnormalities associated with abdominal adiposity with cited MS prevalence of 10 to 30% using Asian-adapted definitions of obesity (BMI ≥ 25 kg/m²) and increased WC (males, ≥ 90 cm, females, >80 cm) (Nestel, et al., 2007). Defining obesity in the different Asian populations has become critical with the generally accepted observation that metabolic risks are greater in Asians than Caucasians at a given BMI. The inter-ethnic differences in percent body fat at a given BMI and in the metabolic responses to fatness have to be considered in setting which appropriate cut-offs to use for Asians in general and for individual ethnic groups (Pan and Yeh, 2008).

Considerations of the ethnic differences in abdominal and visceral fat distribution began early in the Asia-Pacific region. The influence of dietary patterns and physical activity on fat distribution and the development of MS even at lower or normal BMI supported the perspective that lower optimal cut-offs should be used not only for screening but also for strategies for intervention. Attention to lifestyle modification has been pushed early on in the Asia-Pacific region through public health initiatives to stem the tide of obesity and metabolic syndrome (Gill, 2001, Sullivan, 2001).

Recent systematic reviews however showed that the rising problem of MS in Asia remains staggering. Data from 15 Asia-Pacific countries showed the range of the prevalence rates of MS from a low of 11.9% in the Philippines to a high of 49% in urban Pakistan. Higher prevalence in women and in urban dwellers was consistent findings. Temporal trends were available for China, South Korea and Taiwan and all showed increasing prevalence for all three countries from 1993 to 2009. Despite differences in methodology, diagnostic criteria and age of subjects studied, MS is of epidemic proportion in the Asia-Pacific region, with nearly one-fifth of the adult population affected by MS in most countries (Ranasinghe et al., 2017).

Similar trends were reported in South Asia in a recent systematic review of 16 MS population-based prevalence studies from 5 countries. Four definitions of MS were used and the weighted mean prevalence rates of MS were 14.0% (WHO), 26.1% (ATPIII), 29.8% (IDF) and 32.5% (modified ATPIII). Half of the study population had low HDL-C levels and had hypertension. In general, females had a higher prevalence of MS and were more likely to have low HDL-C levels and central obesity. Males, on the other hand, were more hypertensive. These gender-based findings are consistent with the MS profile in Filipino and other Asian populations. Research remains limited despite the enormous burden of MS especially in Asian populations (Aryal and Wasti, 2006).

METABOLIC SYNDROME IN MIGRANT FILIPINOS AND MIGRANT ASIANS IN WESTERN COUNTRIES

Emerging data have shown that cardiometabolic diseases are common in Asian Americans despite mean lower BMI. Asian Americans are the fastest growing ethnic group in the US, numbering over 18 million in 2011. Filipino Americans (3.4 millions) are second only to the Chinese Americans (4.0 millions) and followed by Asian Indians (3.2 millions) and the rest of the migrant Asian population (Vietnamese, Korean and Japanese) (Hsu, et al., 2015). Striking differences in the risk of CVD, obesity, type 2 diabetes mellitus, hypertension, and other CVD risk factors are observed across the Asian-American population (Narayan et al., 2010). The large and the rising number of Asian Americans and their apparent high cardiometabolic risk present an important public health challenge needing better understanding and timely intervention (Palaniappan et al., 2011).

Seminal work by Araneta et al., showed that Filipina women aged 50 to 69 years, compared to Caucasian women, had larger WC and higher percentages of truncal fat, were less likely to be obese, less likely to smoke, consume alcohol, or take postmenopausal estrogen, and had lower HDL-C levels. Filipina women had higher prevalence of type 2 diabetes (36% vs 9%) and MS (34 vs. 13%). A total of 10% of Filipinas with diabetes were obese, compared with over 30% of Caucasians with diabetes. The high prevalence of diabetes in a non-obese ethnic group led to a realization that there is diversity in the development of diabetes across populations and that this high diabetes risk might be missed if Western standards of obesity were applied (Araneta et al., 2002).

Subsequent studies indicated that many Filipino Americans suffer from chronic illnesses, particularly type 2 diabetes, hypertension and dyslipidemia and central adiposity is a common. MS was seen in 18.3% of Filipino American men and women in Clark County, Nevada. Abdominal obesity was seen in 80.6%; hypertension in 47.7%; overweight in 36.7%; and type 2 diabetes in 11.7% (Dalusung-Angosta, 2013). Review of literature on the cardiovascular health of Filipinos in the US from 27 published studies concluded that Filipino Americans were at high risk for CVD, hypertension, type 2 diabetes and MS at lower BMI levels (Abesamis et al., 2015). A cross-sectional study of 335 Filipinos living in Rome, Italy similarly showed high prevalence of abdominal obesity (52.5%), BMI ≥ 25 kg/m² (44.5%), diabetes (6%), and hypertension (9%). Age and WC were associated with both diabetes and hypertension (Gentilucci et al., 2008).

Patterns seen in Filipino and Asian populations manifested as well in Asian Americans, similarly requiring the need to define obesity indices to better predict risk of developing diabetes and hypertension. In the Filipino American women cardiovascular study, using Asian-specific thresholds for BMI, WC and WHR increased the accuracy of prediction (Battie, et al., 2016). The high incidence of type 2 diabetes in non-obese Asian Americans, particularly Asian Indian and Filipinos, led to the recommendation that screening for type 2 diabetes in these populations should start at BMI of 23kg/m² (Wang et al., 2011, Hsu et al., 2015). Differences in the body fat percentages and body fat distribution are evident not only between Asian Americans and other ethnic groups but also between Asian Americans and Asian immigrants. These differences may largely affect susceptibility to developing cardiometabolic diseases (Alpert and Thomason, 2016, Unjali et al., 2017). Better measures of obesity, lower cut-offs for BMI, WC and WHR as indices of cardiometabolic risk, and

even newer indices such as triglyceride glucose (TyG), TyG waist circumference (TyG-WC), TyG-BMI and visceral adiposity index (VAI) may be helpful in predicting risk of developing cardiometabolic diseases, especially type 2 diabetes (Zheng, et al., 2016).

CONCLUSION AND RECOMMENDATIONS

Metabolic syndrome, as a public health and a clinical problem, develops along with increasing obesity. Distinct characteristics between individuals and between populations dictate the attendant cardiometabolic risk in metabolic syndrome. Filipinos, like other Asians, appear to develop metabolic syndrome at lower or even normal BMI levels and this observation maybe explained by higher visceral fat percentages. Gene-environment interaction evidently happened when westernization altered the lifestyle, dietary and physical activity patterns that led to obesity and metabolic syndrome. However, the similarities in cardiometabolic features in Philippine-based Filipinos and migrant Filipinos, as well as Asian residents and migrant Asians, are evidences of strong genetic influences in the disease causation. Characterization of the genetic factors underlying metabolic syndrome will help towards its better understanding, prevention and management. Definition of the syndrome with a universally accepted set of criteria with adjusted cut-offs for ethnic groups should be a goal so that future studies have standardized definitions, making comparisons meaningful. Population-based surveys on metabolic syndrome should be continued along with intervention studies to minimize, if not prevent, the attendant cardiometabolic risk.

Chapter 244

BODY MASS INDEX, PERCENT BODY FAT AND FAT MASS INDEX AS SCREENING TOOLS FOR GENERAL OBESITY AMONG ADULT FEMALES OF AMRITSAR (PUNJAB)

Ramanpreet Randhawa* and Sharda Sidhu

Department of Human Genetics, Guru Nanak Dev University,
Amritsar, Punjab, India

INTRODUCTION

Obesity has emerged as a chronic nutritional disorder almost three decades ago and still continues to escalate its dimensions as one of the most serious considerable non-communicable public health hazard (WHO, 2013). It is now so common that in many environments it is replacing more traditional public health concerns such as undernutrition, infectious diseases, communicable diseases and recognised as a major risk factor for developing hypertension (Warren et al., 2012), lipid disorders (Brown et al., 2000; Sherwood, 2010), glucose intolerance (Kannel, 1987), T2DM (Kahn et al., 2006), heart disease (Taylor et al., 2010), stroke (Oeschet al., 2017), osteoarthritis (King et al., 2013), CVDs (Vangaal et al., 2006), certain cancers (Singhal et al., 2013) and all-cause morbidity and mortality (WHO, 2000; Dalton et al., 2003; Kopelman et al., 2006; Whitlock et al., 2009; Shukla et al., 2014). It is estimated that 2.8 million people die each year and 35.8 million of global disability-adjusted life years (DALYs) across the globe are caused by overweight and obesity (WHO, 2016). The worldwide prevalence of obesity nearly tripled between 1975 and 2016. Very recent data shows that globally 650 billion adults (≥ 18 years) were observed to be obese. In other words, 13% of the world's adult population was diagnosed as obese, out of which 11% of males and 15% of females manifested obesity (WHO, 2016; Behl and Misra, 2017; Meharda et al., 2017). Obesity can be measured in two ways i.e., general obesity and central/abdominal obesity. The

accumulation of fat to that extent that can impair health is known as general obesity. It is prime most important health concern especially among women (Amugsi et al., 2017). It is a critical force behind the progression of an asymptomatic cluster of non-communicable diseases called as metabolic syndrome (Grundy, 2004). However, obesity is not only pivotal cause for the occurrence of metabolic and cardiovascular diseases but also responsible for social stigmatization, psychosocial stress and psychological morbidity (Geiss et al., 2001; Kraig and Keel, 2001). Furthermore, the prevalence of obesity is more pronounced among those residing in the urban areas as compared to rural areas (Bhadra et al., 2005; Senet al., 2013; Kamboj et al., 2017). Currently, the obesity has attained an alarming figures in our nation with approximately 30-65% of adult urban Indians is either overweight, or obese (Mondal and Sen, 2014; Pradeepa et al., 2015). Importantly, this predominance is due to rapid demographic transitions, nutrition transitions and socioeconomic transitions. India, especially Punjab, is a unique example of such transitions, because it has undergone such transitions at a rate much faster than other states of India. However, to the best of my knowledge, there is no published data illustrating the comparative picture of general obesity among adult women using anthropometric and body composition variables from Amritsar. Therefore, in the present study, an attempt has been made to generate baseline data about the prevalence of general obesity among adult females of Amritsar on applying Body Mass Index (BMI), Percent Body Fat (PBF) and Fat Mass Index (FMI) criteria.

MATERIALS AND METHODS

The data for the present cross-sectional study was collected from adult females ranging in age 40-65 years and residing in various urban and rural areas of Amritsar district during the period from June 2013 to September 2016 by using a convenient sampling method. The participants were found in their homes and data was collected from door to door. At each urban and rural area, a uniform protocol of recruitment was followed. Ethical clearance from the Institutional Ethics Committee of Guru Nanak Dev University, Amritsar was obtained prior to carrying out the study.

The study group included 1520 females, out of which, 800 females were urban and 720 females were rural. First of all, women were taken into confidence and then contacted for the study according to their convenience and prior appointment. After fully explaining the nature, procedure, aims and objectives of the study to all the females in Punjabi language, verbal as well as written informed consent was obtained. In person interaction provides an opportunity to the investigator to extract maximum information from the participant about socio-demographic characteristics (name, caste, age and type of family), socioeconomic status (education, occupation and income), lifestyle habits (dietary pattern, physical activity pattern and sedentary behaviour) and menstrual status (regular/irregular/completely stopped) from each subject by investigator herself after ensuring confidentiality of the information. Anthropometric measurements (body weight, height) were taken on each subject using standard methodology given by Weiner and Lourie (1981) while subjects were lightly clothed and wore no shoes. Body weight was measured to the nearest 0.1 kg using automated calibrated electronic scale. Standing height was measured without shoes to the nearest 0.5centimetre using

anthropometric rod. From height and weight measurements, BMI was calculated by dividing weight in kilograms with height in metre squared as follows:

$$\text{BMI} = \text{Weight (kg)} / (\text{Height})^2 \text{ (m)}.$$

The suggested critical limits of BMI by WHO (2000) were used for the assessment of general obesity:

Category	WHO (2000) cut-offs
	BMI (kg/m ²)
Underweight	<18.5
Normal	18.5-22.9
Overweight	23.0-24.9
Obesity	≥25

Per cent Body Fat (PBF) is the percentage of total body weight that consists of fat only not fat-free mass (water, muscle, bone and vital organs). It is evident from the published literature that no criterion for the assessment of body composition has been recommended for South-Asians. Therefore, following criterion of PBF given by Gomez-Ambrosi et al. (2012) was used for the assessment of general obesity among adult females:

Category	PBF cut-offs
Normal	≤30
Overweight	30.1-34.9
Obese	≥35

Fat Mass Index (FMI) estimate or quantify fat stores accurately is the integral part of the prevention and treatment of obesity-related conditions. A potential, more simplified, accurate and highly useful indicator of body adiposity in field research is FMI. This index was first introduced in a study involving nutritional assessment (Van Itallie, 1990) and requires information on body height and fat mass content for calculations. It was calculated by dividing total body fat (kg) by square of height (m).

$$\text{FMI} = \text{Fat mass (kg)} / (\text{Height})^2 \text{ (m)}.$$

In the present study, the prevalence of general obesity was determined using FMI levels divided into separate quartiles for females. Following FMI quartiles recommended by Liu et al. (2013) were used for the assessment of general obesity:

Quartiles	FMI cut-offs (kg/m ²)	Category
Q1	<5.25	Underweight
Q2	5.25-6.32	Normal
Q3	6.33-7.93	Overweight
Q4	≥ 7.93	Obese

The data was analysed using the Statistical Package for Social Sciences (SPSS Inc, Chicago, IL, USA version 21). Mean and standard deviations were calculated for continuous variables and percentage for categorical variables. In order to test the level of significance of differences between the baseline characteristics of urban and rural women, Student's t-test was applied. The Chi-square test was applied to compare differences between the proportions.

RESULTS

The results of the present study have been arranged in tabular form as well as graphical form, wherever possible, along with the statistical interpretation.

Distribution of Participants According to Place of Residence

Out of 1520 subjects, 52.6% (800) females were urban and 47.4% (720) females were rural (Table 1, Figure 1).

Table 1. Distribution of participants according to place of residence

Category	Adult Females
Urban	52.6 (800)
Rural	47.4 (720)
Total	100.0 (1520)

Figures in parentheses indicate the number of subjects.

Figure 1. Histogram showing the distribution of adult females according to place of residence.

Anthropometric and Body Composition Variables Studied among Adult Females of Amritsar

Table 2 shows mean ($\pm$ SD) values of anthropometric and body composition variables studied among adult Amritsar females after stratification of females according to the region. Considering anthropometric variables, among urban and rural females, it was noticed that urban females were having more weight (65.90 ± 14.3 kg) than rural females (63.47 ± 14.0 kg) whereas rural females were taller (155.98 ± 6.0 cm) than urban females (154.91 ± 5.9 cm) and

the differences in weight ($p<0.01$) and height ($p<0.05$) were statistically significant between urban and rural females. Mean value of Body Mass Index (BMI) among urban and rural females was 27.45 ± 5.7 kg/m² and 26.09 ± 5.7 kg/m², respectively, and the difference in the mean values of BMI between the two groups was highly significant ($p<0.001$).

Table 2. Mean and standard deviation ($\pm$ SD) values of anthropometric and body composition variables of Amritsar adult females studied

Variable	Total (1520)				't'-value
	Urban (800)		Rural (720)		
	Mean	SD	Mean	SD	
Weight (kg)	65.90	14.3	63.47	14.0	3.345**
Height (cm)	154.91	5.9	155.98	6.0	3.456*
BMI	27.45	5.7	26.09	5.7	4.632***
TBF	33.16	8.0	28.93	9.3	6.019***
PBF	44.44	10.9	43.82	9.7	1.164***
FFM	37.32	7.4	38.23	9.8	2.019*
FMI	13.92	5.4	12.54	4.3	5.754***

*Significant at $p<0.05$, **Significant at $p<0.01$, ***Significant at $p<0.001$.

BMI: Body Mass Index (kg/m²), FFM: Fat-Free Mass (kg),

FMI: Fat Mass Index (kg/m²), PBF: Percent Body Fat,

TBF: Total Body Fat (kg).

In context to body composition variables, compared to rural counterparts, higher mean value of total body fat (urban 33.16 ± 8.0 kg vs. rural 28.93 ± 9.3 kg, $p<0.001$) was observed in urban females. In addition to this, the differences were found to be highly significant ($p<0.001$ for both variables) in the mean values of per cent body fat (urban: 44.44 ± 10.9 vs. rural: 43.82 ± 9.7) and fat mass index (urban 13.92 ± 5.4 kg/m² vs. rural 12.54 ± 4.3 kg/m²) between the two groups. In contrast to this, rural females were found to have significantly ($p<0.05$) elevated levels of fat-free mass (urban 37.32 ± 7.4 kg vs. rural 38.23 ± 9.8 kg) than urban females.

Assessment of General Obesity

BMI criterion of WHO (2000): Table 3 and Figure 2 shows the percentage prevalence of obesity in the study females using WHO (2000) criterion of BMI for Asian populations. According to this classification, the overall prevalence of obesity was 61.4% whereas 12.8% females were overweight, 19.6% females were normal and only 6.2% females were underweight. After stratification of females according to region, it was noticed that the prevalence of obesity was 68.7% and 53.3% among urban and rural females, respectively. The difference in the percentage prevalence of obesity between urban and rural females was found to be statistically significant ($\chi^2=37.37$, $df=1$; $p<0.001$). It is clear from the table that the prevalence of overweight, normal and underweight urban females was 10.6%, 15.4% and 5.3%, respectively, whereas the corresponding figures for rural females were 15.3%, 24.3% and 7.1%, respectively.

Table 3. Percentage prevalence of General Obesity according to Body Mass Index (WHO, 2000) criterion among adult females of Amritsar

CATEGORY	ADULT FEMALES			
	Urban (800)	Rural (720)	Total (1520)	χ^2 -value
Underweight	5.3 (42)	7.1 (51)	6.2 (93)	1.91
Normal	15.4 (123)	24.3 (175)	19.6 (298)	18.61***
Overweight	10.6 (85)	15.3 (110)	12.8 (195)	6.93**
Obese	68.7 (550)	53.3 (384)	61.4 (934)	37.37***

Figures in parentheses indicate the number of subjects.
*Significant at $p<0.05$, **Significant at $p<0.01$, ***Significant at $p<0.001$.

Figure 2. Histogram showing the percentage prevalence of underweight, normal, overweight and obese among adult females according to Body Mass Index (WHO, 2000) criterion.

Percent Body Fat (PBF)

It is defined as the proportion of total body fat mass of total body weight and it accurately predicts cardiovascular risks than BMI (Zenget al., 2012). Table 4 and Figure 3 depict the percentage prevalence of obesity assessed with the help of per cent body fat determined by Bioelectrical Impedance Analysis (BIA) among females according to per cent body fat criterion (Gomez-Ambrosiet al., 2012). The overall prevalence of obesity was 80.3% (urban 83.2% vs. rural 76.9%). On the other hand, 11.5% females were observed as overweight (urban 8.5% vs. rural 14.9%) and 8.2% as normal (urban 8.3% vs. rural 8.2%). The difference in the percentage prevalence of obesity between urban and rural females was statistically significant ($\chi^2=9.12$, $df=1$; $p<0.01$).

Figure 3. Histogram exhibiting the percentage prevalence of normal, overweight and obese among adult females using Percent Body Fat (PBF) criterion.

Table 4. Percentage prevalence of General Obesity using Percent Body Fat (PBF) criterion as given by Gomez-Ambrosi et al. (2012) among adult females of Amritsar

CATEGORY	ADULT FEMALES			
	Urban (800)	Rural (720)	Total (1520)	χ^2 -value
Normal	8.3 (66)	8.2 (59)	8.2 (125)	–
Overweight	8.5 (68)	14.9 (107)	11.5 (175)	14.43***
Obese	83.2 (666)	76.9 (554)	80.3 (1220)	9.12**

Figures in parentheses indicate the number of subjects.

*Significant at $p < 0.05$, **Significant at $p < 0.01$, ***Significant at $p < 0.001$.

Fat Mass Index (FMI)

Fat mass index was first introduced by Van Itallie et al., (1990) and is calculated by taking the total body fat mass component from bioelectrical impedance analysis and dividing it by height squared. Table 5 and Figure 4 demonstrate the percentage prevalence of obesity among participants using fat mass index criterion (Liu et al., 2013). In the present sample, the overall prevalence of obesity was 88.5%. In addition to this, 5.8%, 2.9% and 2.8% females were encountered as overweight, normal and underweight, respectively. Region-wise prevalence of obesity in the study participants was almost similar (urban 88.7% vs. rural 88.4%) and the difference between the two groups was statistically non-significant. Further, it was noticed that 4.6% (urban) and 7.1% (rural) females were overweight, 3.8% (urban) and 1.9% (rural) were normal, and 2.9% (urban) and 2.6% (rural) were underweight.

Table 5. Percentage prevalence of general obesity using Fat Mass Index (FMI) quartiles as given by Liu et al. (2013) among adult females of Amritsar

Category	Urban (800)	Rural (720)	Total (1520)	χ^2 -value
Underweight	2.9 (23)	2.6 (19)	2.8 (42)	0.02
Normal	3.8 (30)	1.9 (14)	2.9 (44)	3.79
Overweight	4.6 (37)	7.1 (51)	5.8 (88)	3.76
Obese	88.7 (710)	88.4 (636)	88.5 (1346)	0.03

Figures in parentheses indicate the number of subjects. *Significant at $p < 0.05$, **Significant at $p < 0.01$.

Figure 4. Histogram demonstrating the percentage prevalence of underweight, normal, overweight and obese among adult females using Fat Mass Index quartiles.

DISCUSSION

The anthropometry is pioneer in the series of obesity assessment methods in large field surveys and epidemiological studies. The measurement of anthropometric index known as Body Mass Index (BMI) is found as the simplest, easiest, non-invasive and cost-effective potential indicator of medical complications of obesity (Ouyang et al., 2015; Choi et al., 2017). In the nineteenth century, the mathematician and social statistician Adolphe Quetelet observed that the weight of the average person was proportional to the square of the height. The ratio of body weight measured in kilograms divided by the square of the height measured in metres was termed as quetelet's index and later renamed as body mass index (Keys et al., 1972). The simplicity and ease of measurement have entrenched the widespread use of BMI as a marker of adiposity not only for epidemiological purposes but also in clinical practice. In the present study, the mean values of BMI observed in urban and rural females were $27.45 \pm 5.7 \text{ kg/m}^2$ and $26.09 \pm 5.7 \text{ kg/m}^2$, respectively and the difference in the mean values of BMI between urban and rural females was statistically significant ($p < 0.001$).

WHO (2000) classification of BMI has been recommended for Asian population including lower cut-off of BMI for the assessment of obesity because Asian people depict substantial risk of T2DM and CVDs at lower weight or fat accumulation (WHO, 2004). The overall prevalence of obesity was found as 61.4% on applying BMI criterion of WHO (2000) in the females studied (Table 3). The difference in the prevalence of obesity between urban females (68.7%) and rural females (53.3%) was statistically significant ($\chi^2 = 37.37$, $df = 1$, $p < 0.001$). The results of the present study were compared with the general female populations of different parts of India to expedite a relative estimation of obesity prevalence. Table 6 presents the percentage prevalence of obesity according to BMI criteria of WHO (2000) among women residing in various urban regions of India. Nonetheless, the extent of obesity is not firmly comparable because of divergence in the methods of measurements, dissimilarity in sample size and study design, difference in age and socioeconomic status of subjects, ethnic variation, diverse food habits, their lifestyle and periodic dissimilarities in the studies. It is very clear from this table that the prevalence of obesity using BMI criterion of WHO (2000) among urban Indian females varies considerably from one region to another region with rates as high as 71.8% among females of West Bengal (Das and Bose, 2006) and as low as 15.6% among females of South Delhi (Misra et al., 2001). After three years in 2003, the prevalence of obesity was observed to be four times higher i.e., 66.7% in New Delhi females depicting a rising trend with the passage of time under similar geographical conditions (Misra et al., 2003). Apparently, the estimates of obesity in the present study were observed to be close to the females of New Delhi. In addition to this, Reddy et al. (2002) performed an epidemiological study among New Delhi females and examined 48.0% females as obese. In the western region, three cross-sectional studies were performed by Malshe and Udipi (2017), Rathi et al. (2014) and Senet et al. (2009), and reported 43.6%, 40.5% and 29.3% females as obese residing in Mumbai city and Pune city of Maharashtra and Jalpaiguri, West Bengal, respectively. Moreover, 30.2% prevalence of obesity was assessed among adult females of Rajasthan by Gupta et al. (2002). In the Southern region, the most latest study for the assessment of obesity among 1000 Karnataka females ranging in age 15-64 years was accomplished by Nagendra et al. (2017) and revealed 34.9% obesity. In an earlier study carried out in Dharwad, Dandeli and Belgaum districts of Karnataka, 63.3% females yielded

obesity (Goyal et al., 2012). Among Chennai females, Anuradha et al. (2011) observed the prevalence of obesity as 19.8% whereas 31.2% females were noticed as obese by Deepa et al. (2009). In the eastern region, a very recent cross-sectional study was executed by Senet al. (2017) and analysed 48.7% females falling in the category of obesity.

The prevalence of obesity among women of Punjab has also been studied by other investigators. Girdhar et al. (2016) and Singh et al. (2015) carried out two cross-sectional studies in Ludhiana on 324 females (20-60 years) and 618 females (25-64) of Ludhiana and diagnosed 29.6% and 28.8% females as obese according to BMI criterion of 2000 and 1998, respectively. On applying WHO (2000) criterion of BMI, the prevalence of obesity varied from 23.2 - 34.3% among 1088 females of Punjab ranging in age 45-69 years and 18-44 years, respectively (Tripathy et al., 2016). In Amritsar, the figures of obesity were found to be 56.4% on investigating 172 females by Randhawa and Sidhu (2014). One of the large sample size (N=3000) study conducted in Punjab by Sidhu and Randhawa (2014) reported 33.4% females as obese using Asian BMI cut-offs (≥ 25 kg/m²). In another study on Punjabi urban females, Sidhu et al. (2005) found 21.1% obese females as per BMI (WHO, 1998) criterion of obesity. Sidhu and Prabhjot (2004) performed a study on 500 Punjabi women and reported 15.0% prevalence of obesity. Sidhu and Tatla (2002) studied adult Punjabi females and reported 25.3% of them as obese (BMI ≥ 30.0 kg/m²). It can be deciphered from this table that Amritsar females were noticed to be more obese as compared to females residing in other districts of Punjab.

Table 7 presents a compilation of studies demonstrating the prevalence of obesity reported in rural females of India. A recent study performed by Bharali et al. (2017) involving adult Nyishi tribal females in Arunachal Pradesh found 9.5% prevalence of obesity according to WHO (2000) criterion of BMI. In addition to this, two cross-sectional studies were carried out among tribal females hailing from Assam (Mondal et al., 2016) and Manipur (Mungreiphy and Kapoor, 2008) and examined 15.2% and 27.1% females as obese (BMI ≥ 25 kg/m²). Furthermore, 36.9% females of Haryana aged ≥ 20 years were categorized as obese (BMI ≥ 25 kg/m²) during a population-based study attempted by Verma et al. (2016). Another study, among rural females of Tamil Nadu, the prevalence of obesity was found to be 21.2% by the WHO (2000) classification of BMI (Little et al., 2016). Assessment of obesity among females of union territory named as Puducherry was accomplished by Shrivastava et al. (2015) and findings of the study revealed that 27.3% females were obese as per BMI (2000) classification.

In the same year, a community-based study was conducted in Kerala by Bindhu et al. (2014) revealed 44.7% females as obese using BMI (≥ 25 kg/m²) cut-offs. The prevalence of obesity among Tamil Nadu females was studied by Chauhan et al. (2015) and found 23.8% females as obese (BMI ≥ 25 kg/m²). Almost similar prevalence of obesity was encountered among females of Uttar Pradesh (22.0%) and Maharashtra (22.7%) on employing WHO (2000) classification of BMI (Kumar et al., 2014; Rath et al., 2014). The higher rates of obesity (40.0%) were observed in Delhi females by Reddy et al. (2002) using BMI (≥ 25 kg/m²) cut-offs. Other than this, very few studies have been performed in rural areas of Punjab to assess obesity.

Comparison of three major studies conducted by National Family Health Survey (a multicentric study; NFHS-2 during the period from 1998-1999; conducted on 90,000 women in the age group of 15-49 years in 26 states), NFHS-3 (2005-2006, conducted on 1,24,385 women in the age group of 15-49 years in 29 states) and NFHS-4 (2015-2016, conducted on

6,99,686 women in 29 states and 7 union territories) was done. NFHS-2 and NFHS-3 used BMI ≥ 25 kg/m² criterion for the assessment of overweight and obese individuals while in NFHS-4, BMI ≥ 25 kg/m² criterion was applied for the assessment of obese individuals only.

According to these national reports, the prevalence of obesity has elevated among Indian women from 10.6% in NFHS-2 to 12.6% in NFHS-3 and to 20.7% in NFHS-4. This data shows that the prevalence of obesity has increased 10.1 percentage points higher during the period from 1998 to 2016. The prevalence of obesity is dramatically increasing among urban and rural females. It has been reported by NFHS-4 that 31.3% of urban women were obese as compared to 23.5% in NFHS-3 and 9.4% in NFHS-2.

In rural areas, the prevalence of obesity has also risen from 2.6% in NFHS-2 to 7.4% in NFHS-3 and to 15.0% in NFHS-4. These figures depict that the prevalence of obesity has increased 21.9 percentage points and 12.4 percentage points higher among urban and rural females, respectively from NFHS-2 to NFHS-4.

Rural areas of Amritsar district	40-65	720	53.3	Present study

Among Punjabi women, according to NFHS-2 report, the prevalence of obesity was 31.3%, it was 29.9% as per NFHS-3 report but in NFHS-4 report the estimates of obesity were noticed as 31.2%. This shows that there is decline in the prevalence of obesity among Punjabi females from NFHS-2 to NFHS-3 but in NFHS- 4 it was almost similar to the prevalence of obesity reported by NFHS-2. It is evident from these studies that the extent of obesity reported in these studies is not strictly comparable because of the variation in criteria of BMI used. Some of the states and union territories where the prevalence of obesity among women was found to be higher than national prevalence (20.7% in NFHS-4, Table 8) includes Puducherry (36.7%), Punjab (36.7%), Delhi (34.9%), Goa (33.5%), Andhra Pradesh (33.2%), Kerala (32.4%), Daman and Diu (31.6%), Odisha (31.3%), and Tamil Nadu (30.9%).

Table 8. Prevalence of obesity among Indian females according to National Family Health Survey (NFHS-4, 2015-2016) report

States	Obesity		
	Urban	Rural	Total
Andhra Pradesh	45.6	27.6	33.2
Arunachal Pradesh	25.7	16.3	18.8
Assam	26.1	10.9	13.2
Bihar	23.5	9.7	11.7

Dadra and Nagar Haweli	34.2	6.9	19.2
Daman and Diu	32.7	29.0	31.6
Lakshadweep	42.4	28.2	41.4
Puducherry	38.1	33.6	36.7

Among urban and rural areas of Punjab, the epidemic of obesity has also increasing rapidly. NFHS-4 conducted field work on 19,484 urban and rural females during the period from 28 January, 2016 to 20 June, 2016 and observed that the prevalence of obesity was 32.4% in urban females and 30.6% in rural females. It is concluded from the present study that prevalence of obesity in Amritsar females is about 1.9 times and 2.9 times higher than the prevalence of obesity in Punjabi females and Indian females reported in NFHS-4, respectively.

Results from the 2011–2012 National Health and Nutrition Examination Survey (NHANES) among adults aged 20 and over, documented 35.1% prevalence of obesity (Fryar

et al., 2014) which is far less than reported in the present study of adult Jat-Sikh females of Amritsar. A total of 2,50,651 women (aged 15–49 years) from 32 Sub-Saharan countries were studied between January 2005 and December 2013 under Demographic and Health Survey (DHS), nationally representative cross-sectional study revealed 23.0% as the highest obesity estimates in Swaziland women (Neupane et al., 2016) which is no doubt less than assessed in the present study adult females. Ellulu et al. (2014) quoted that obesity is one of the most glaring body condition which increase the chances of a person to be the victim of various other non-communicable diseases and reported that in Europe, the figures of obesity among females were 22.0%, 17.0%, 16.0%, 7.0% and 6.0% residing in Germany, Latvia, Ireland, Sweden and Norway, respectively which are very less than present findings. Evidences of obesity from Pacific Islands put forward 79.0% obesity among females of Nauru which is higher than obesity found in Amritsar females. Moreover, 50.0% obesity was yielded by Cook Islands females which are in concordance with the current study estimates. Amugsi et al. (2017) elucidated increase in obesity among women hailing from urban settings of 24 African countries. The results documented that Egypt country, earlier ranked among the countries in the world with the most obese people reported 39% females as obese followed by Ghana (22%). The findings of the present study depicted that urban females had even higher prevalence of obesity than Egypt females residing in urban settings. It is absolutely marked from the comparative profile of Indian literature (Table 6) that obesity assessed in the adult urban Amritsar females in the present study is quite high as compared to most of the other national studies.

The present study investigated that obesity estimates were higher among urban dwellers than rural inhabitants. The overindulgence in high calorie diet and indoor sedentary leisure activities may contribute the higher risk of obesity among urban dwellers. The present findings are in agreement with urban-rural disparity study of Yangon region, Myanmar (Htet et al. 2016). They performed two cross-sectional studies in urban and rural regions of Yangon region including 379 (urban) and 362 (rural) females ranging in age 25 to 74 years between September and November of 2013 and 2014, respectively, and published results demonstrated that urban women had significantly higher prevalence of obesity (urban: 17.3% vs. rural: 11.5%) than rural women. In accordance with few other researchers (Sophal et al., 2010; Benjakul et al., 2013), the estimates of obesity are generally worse for urban populations than rural populations. Duda et al. (2007) also postulated that obesity was found to be more prevalent in the urban rather than rural areas. Data from the 2000–2001 Behavior Risk Factor Surveillance System (BRFSS) and the 1997–1998 National Health Interview Survey (NHIS) contradict present findings by revealing obesity prevalence higher in rural regions compared to urban counties (Patterson et al., 2004; Jackson et al., 2005). Similarly, National Center for Health Statistics (NHANES 2005–2008) included 7,325 urban and 1,490 rural adults ranging in age 20 to 75 years to assess the health and nutritional status of US population and demonstrated that rural regions significantly affected with higher rates of obesity than urban counterparts (Befortet al., 2012). It is striking to know that the prevalence of obesity among adult urban and rural females of Amritsar is tremendously higher than developed nation US, urban and rural populations (CDC, 2011; Hill et al., 2014). Disparity comes into existence from ethnic, nutritional, demographical and socioeconomic population dissimilarities.

With the advancement in technologies in digital age; more sophisticated measurement tools for the assessment of body composition rather than body mass is increasingly used to study obesity-associated health risks (Atanas and Georgi, 2011; Krachler et al., 2013). These

health conditions are attributed to distribution and pattern of fat in the body constituting total body weight. The true body fatness may be better evaluated by assessment of per cent body fat and fat-free mass (Thibault and Pichard, 2012). Therefore, obese individuals can be examined precisely by measuring body composition which has been considered as a better approach in the evaluation of nutritional and health status (Willet et al., 2006; Peppia et al., 2012; Zeng et al., 2012; Bintvibok et al., 2013). Body composition methods measure tissue conductivity of a body segment under stable conditions which is directly proportional to the amount of electrolyte-rich fluid present. Fat is anhydrous and their all body water and fluids are found in fat free mass body component (Heymsfield et al., 1996). Recent development in modern anthropology provided Computed Tomography (CT) scan, Dual-Energy X-ray Absorptiometry (DEXA) and Bioelectrical Impedance Analysis (BIA) devices for body fat measurement. CT scan and DEXA equipment estimates per cent fat mass with suitable accuracy and have emerged as the reference method for estimating body composition (Heymsfield et al., 1996). However, both these procedures drawbacks are radiation exposure, relatively high cost, non-portable and limited approachability for epidemiological studies. BIA depicted excellent correlation with CT scan and DEXA in assessing per cent body fat and is believed to be best replacement for these high-priced techniques to screen large group of individuals (Ryo et al., 2005; Jeong et al., 2006; Xu et al., 2011). Bioelectrical Impedance Analysis (BIA) has been extensively recognised as one of the simplest, safest, valid, portable and non-invasive procedure to determine the individual's body composition, particularly body fat (Houtkooper et al., 1996; Kyle et al., 2004; Rana and Sidhu, 2012; Rani and Gupta, 2014; Randhawa and Sidhu, 2014) and Percent Body Fat (PBF) is the percentage of total body weight that is only fat.

Table 9. Percentage prevalence of general obesity among females reported in various Indian studies using PBF cut-offs

Place/Area/State	Age group (years)	No. of females	PBF cut-offs used	Percentage prevalence	Investigator
Urban					
Mumbai	21-45	1500	>30	59.5	Malshe and Udipi (2017)
Raipur, Chhattisgarh	25-50	70	>30	70.0	Verma et al. (2015)
Amritsar	30-50	172	≥35	60.4	Randhawa and Sidhu (2014)
Amritsar	20-25	150		36.0	Rana and Sidhu (2012)
Hindu Bengali Females	20-50	854	≥30	36.5	Bhadra et al. (2005)
New Delhi	≥18	362		40.2	Misra et al. (2001)
Urban areas of Amritsar district	40-65	800	≥35	83.2	Present study
Rural					
Haryana	≥ 20	540	>30	43.1	Verma et al. (2016)
Rural areas of Amritsar district	40-65	720	≥35	76.9	Present study

In the present study, the mean values of percent body fat observed in urban and rural females were 44.44 ± 10.9 kg/m² and 43.82 ± 9.7 kg/m², respectively and the difference in the mean values of percent body fat between urban and rural females was statistically significant ($p < 0.001$). According to menstrual status, among urban and rural females, it was noticed that postmenopausal females had significantly ($p < 0.001$) higher mean value of percent body fat than premenopausal females (Table 2). The overall prevalence of obesity according to percent

body fat criterion was 80.3% (urban: 83.2% vs. rural: 76.9%) in the study population (Table 4). The difference in the prevalence of obesity between urban and rural females was statistically significant ($\chi^2=9.12$, $df=1$, $p<0.01$).

National studies for the assessment of obesity using PBF criterion was very scarce or may be unpublished in the literature. It is evident from Table 9 that adult Jat-Sikh urban females of Amritsar reported two times more PBF as compared to females of capital city of nation (Misra et al., 2001). It is worth mentioning that even rural counterparts of the present study reflected humongous accumulation of body fat than other female populations of country. This shows that Punjabi females have more propensity of amassing body fat due to their dietary habits and sedentary lifestyle pattern. Malshe and Udipi (2017) exhibited 59.5% females of Mumbai as obese (PBF >30). The females studied by Verma et al. (2015) yielded 70.0% obesity according to >30 criterion of PBF. In Amritsar, two studies were attempted within a gap of two years and to our surprise estimates of obesity regarding deposition of body fat in the concerned area females raised two fold from 36.0% (Rana and Sidhu, 2012) to 60.4% (Randhawa and Sidhu, 2014) with the passage of time. Among Hindu Bengali females, the figures of obesity were 36.5% on applying ≥ 30 cut-offs of PBF (Bhadra et al., 2005). With respect to rural dwellers, only one study was available which was performed by Verma et al. (2016) in Haryana and estimated that 43.1% females were inclined towards the excess building-up of body fat when >30 PBF criterion was incorporated. It is evident that both urban and rural females of Amritsar manifested quite high prevalence of general obesity using PBF cut-offs.

Furthermore, in the studied population, the difference was found to be highly significant ($p<0.001$) for fat mass index (urban 13.92 ± 5.4 kg/m² vs. rural 12.54 ± 4.3 kg/m²) between urban females and rural females (Table 2). In the present sample, the overall prevalence of obesity was 88.5% using FMI criterion (Table 5). Region-wise prevalence of obesity in the study participants was almost similar and the difference between the two groups was statistically non-significant. Unfortunately, there is no report in the current literature regarding the prevalence of obesity on the basis of FMI on Indian females. The outcome drawn by the results of the present study with respect to the assessment of general obesity confirms that adult Jat Sikh females of Amritsar were observed to be more obese using body composition method than the most frequently used diagnostic tool i.e., BMI. In other words, FMI assessed the highest prevalence of obesity followed by PBF and BMI. However, despite of the common usage of BMI among clinical settings and large scale field studies still its facing criticism in the terms of its diagnostic precision (Romero-Corral et al., 2008; Paniagua et al., 2013; Gurunathan and Myles, 2016).

BMI is not reliable to discriminate between total body fat and fat free mass. Even though BMI is the most commonly used index, it does not correspond to fatness uniformly in all populations, and inter-ethnic extrapolations are not possible (Deurenberg et al., 1998). The overestimation of adiposity in muscular body build and underestimation of obesity in the elderly is the evident shortcoming of using BMI (Kyle et al., 2004; Pasco et al., 2012; Liu et al., 2013). Therefore, it introduces misclassification problem by not providing information about fat free components (bone mass, muscle mass, mineral content and body fluids) for a given BMI across age, gender and ethnicity (Whitlock et al., 2009). Thus, resulting in variability in different individuals and populations (Gomez-Ambrosi et al., 2012). Various scientists (WHO, 1998; Raji et al., 2001; Deurenberg et al., 2002; Rush et al., 2004; Kagawa et al., 2006) reported that Asians like Indians have a smaller body frame and body mass index

classification of obesity based on large framed Euro pid populations may be inappropriate for them. In fact, BMI of 30 kg/m² among Europeans correlate with about 25% of percent body fat content in males and 30% of percent body fat in females, while for same age, gender and BMI; South Asians have an increased percent body fat and lesser fat free mass predicting higher risks for cardiovascular diseases (Bagry et al., 2008; Abdullah et al., 2010). Elucidating from the accumulating results set forth by influential researchers (Raji et al., 2001; Joshi, 2003; Lorenzo et al., 2003; Gupta et al., 2004) that for similar value of BMI, Asian Indians illustrate so called “Asian Indian Phenotype” characterized by less of general obesity as measured by BMI but have significantly large percentages of body fat and greater total abdominal and visceral fat area (McGee, 2005; Darokar et al., 2016) compared with white Caucasians resulting in metabolic disorders at much lower levels of BMI. Therefore, the BMI, usually used in population studies to diagnose obesity is unreliable and necessitate the screening of individuals for distribution of body fat rather than simply measuring the increase of body weight. Soni and Verma (2013) described BIA is the best option to measure body composition in field surveys.

Notably, BIA is dependent not only on body composition (fat mass and fat free mass components) but also on body size (cross-sectional areas in trunk and limbs). Since the proportions of body segments depend not only on weight, age and gender but also on race and ethnicity. Therefore, the estimation equations of percent body fat need to be population-specific and revalidated when applied in population that differs from the one in which original method was developed (Krachler et al., 2013). This seemingly obvious step is often overlooked by researchers (Heymsfield et al., 1996). Moreover, there is inadequacy of literature on population-specific studies to validate these equations. Further studies were warranted to generate consensus on the exact, usable and population-specific cut-offs for both PBF and FMI which can be used to counsel females of different races or ethnicity about their actual risk of morbidity based on their body fat distribution. For instance, to reduce the risk of obesity allied morbidity, White and Hispanic obese women could be advised to reduce their BMI levels 28-29 kg/m² as they have more deposition of body fat for a given BMI (≥ 30 kg/m²) than black women (Rahman et al., 2009). Similarly, ethnic-specific cut-offs of PBF and FMI are required to facilitate the assessment of obesity associated co-morbidities across the globe.

ACKNOWLEDGMENTS

We would like to express our profound gratitude to all the females for their cooperation and contribution towards this study. We are whole-heartedly thankful to Miss Jaspreet Kaur for her assistance in the collection of data. The authors deeply acknowledge the funding received from the Guru Nanak Dev University under the scheme University with Potential for Excellence (UPE) and Centre with Potential for Excellence in Particular Area (CPEPA).

²Biological Anthropology Unit, Indian Statistical Institute,
Kolkata, India

ABSTRACT

Metabolic syndrome (MetS) or Syndrome – X is considered to be a major public health problem in the developed as well as developing countries. Present study has attempted to evaluate the plausible relationship between central adiposity and MetS, among the Bhutias of Sikkim, India. 428 adult Bhutias, an Indian tribe, were systematically chosen from urban and rural areas of the Himalayan State of Sikkim. Blood pressures and anthropometrics along with fasting glucose and lipid profile were recorded from all the participants (aged ≥ 20 years). Data on sociodemographic aspects and selected lifestyle related variables were collected by using pre-tested questionnaires. Prevalence of MetS was found to be significantly higher among the individuals with sedentary lifestyle, those who are engaged in less active job and those who regularly consume alcohol than their corresponding counterparts. After adjusting for significant lifestyle related predictors, abdomen circumference was found to predict MetS significantly. This small scale cross-sectional study evidently found the positive association of central adiposity related measures with MetS.

INTRODUCTION

The World Health Organization (WHO) has considered the Metabolic Syndrome (MetS) as one of the most burning issues pertaining to health research in both developed and developing countries since decades (Alberti and Zimmet 1998). The MetS is a group of several risk factors such as excess body fat or obesity, higher lipid, blood pressure and glucose level, i.e, dyslipidaemia, hypertension and hyperglycaemia, respectively (Reaven 1988; Timer et al. 2000). Later, International Diabetes Federation (IDF) redefined MetS, where central obesity as measured by waist circumference (WC) is considered as the essential constituent (Alberti et al. 2005). Reaven (1988) coined the term ‘Syndrome X’, while for the first time he draw attention to this clustering of physiological abnormalities, mainly in overweight individuals.

The prevalence of MetS and cardiovascular disease (CVD) have radically risen in parallel with the global obesity epidemic (Zimmet et al. 2001; Ford et al. 2002). Study has shown that the development of MetS is based on certain complex interaction between genetics, lifestyles and other metabolic factors (Groop 2000). US population shows a prevalence of MetS of more than 20% (Park et al. 2003), while that of Australia is 35.8% (Vaughan et al. 2009) and of China is 21.3% (Xi et al. 2013). In addition to the developed countries, MetS becomes a burning issue in the health research of the developing countries. Transition from rural way of life to comparatively complex urban lifestyle was frequently reported to be a major causal factor pertaining to this abrupt increase in the prevalence of MetS in the developing nations. Since last two decades, many researchers of different countries have reported the prevalence of MetS. The prevalence of MetS is found to be 28.4% in Indonesia (Soweondo et al. 2010), 16.5% in Japan (Hao et al. 2007), 34.8% in Pakistan (Hydrie et al. 2009), 31.3% in South Korea (Park et al. 2015), 24.3% in Sri Lanka (Katulanda et al. 2012) and 24.6% in India (Ravikiran et al. 2010).

The association of dietary habits and physical activity pattern with MetS has been shown in developing countries (Solomons and Gross 1995). Study among urban population also shows sedentary lifestyle and physical inactivity as imperative factors in developing MetS (Torjensen et al. 1997). It is widely and universally accepted that central obesity in terms of waist circumference (WC) happens to be one of the most important and essential components in identifying MetS (NCEP and IDF). Many studies have reported the association between lifestyle related factors, including psychosocial factors and MetS, along with hypertension, obesity, hypertriglyceridaemia (Everson et al. 2002; Wardle et al. 2002; Brunner et al. 2002).

Among the north Indian population the prevalence of MetS was found to be 22.9% in males, 39.9% in females and 31.6% in total sample considering all ages (Gupta et al. 2004). Study pertaining to MetS among the Indian ethnic populations is almost lacking. However, comparison has been made between the Bhutias of Sikkim and Totos of West Bengal pertaining to MetS and its lifestyle related correlates (Sarkar et al. 2005). The aforementioned data prompted us to carry the present study on examining the association of central adiposity with MetS among the Bhutias, an ethnic group inhabiting the eastern Himalayan State of Sikkim. Specifically, attempt has been made to find out the set of adiposity related variables that are responsible for MetS in this population.

MATERIALS AND METHODS

The Bhutias, inhabiting the town of Gangtok, and also those residing in the rural villages under Ralong Revenue Block of South District were selected as study participants. The individuals of this ethnic group bear Mongoloid features. Agriculture, service in different Government and private sectors, business are their principal ways of earning. Other behavioural and population features can be found elsewhere (Sarkar and Mukhopadhyay 2008).

428 Bhutia individuals of both sexes aged 20 years and above were considered for the study. All the households were considered in case of Ralong Revenue Block and from Gangtok, 100 households were systematically selected. One male and one female, preferably the household head and his wife, were chosen to participate in the present study. Those who were under medication for any chronic disease(s), were excluded from the study. All the parameters pertaining to MetS, viz. blood pressures, lipid profiles, fasting blood glucose, skinfold thicknesses and circumferences were recorded from all the study participants following standard methods and techniques (Lohman et al. 1988). In addition, conicity index was deduced as per universally accepted formula. Summation of six skinfold thicknesses (biceps, triceps, sub-scapular, supra-iliac, abdominal and calf) was used as one of the overall adiposity measures. Bioelectrical impedance was used to know the percent body fat and fat mass of each study participant. Data on socioeconomic and lifestyle related variables (socioeconomic status, alcohol consumption, dietary practices, physical activity pattern) were collected from each study participant with the help of pre-tested questionnaires.

The categorization of the socioeconomic status variables were mentioned in an earlier study among the Bhutias of Sikkim (Mukhopadhyay and Sarkar 2018). Blood pressure (BP) measurements of each study participant were recorded following standard technique (Pickering et al. 2003). The average of two consecutive measurements was used in statistical analysis. Fasting blood glucose was examined by one drop of whole blood with the help of “Accutrend Alfa” glucometer. 2ml. blood sample was collected after 12 hours of fasting for estimating the lipid levels of the study participants. Present study follows the recommended criteria of the International Diabetes Federation (Alberti et al. 2005) for the diagnosis of the MetS (WC: > 94cm for males and > 80cm for females; TG: $\geq 150\text{mg/dL}$; HDL: < 40mg/dL for males and < 50mg/dL for females; SBP ≥ 130 mm Hg and/or DBP $\geq 85\text{mm Hg}$; Fasting blood glucose $\geq 100\text{mg/dL}$). Individuals, who satisfied WC cut-off and any two other conditions from the rest four criteria, were considered as having MetS. Informed consent was obtained from all the study participants before collecting any data.

Statistical Analyses

All statistical analyses have been done with the help of SPSS 16.0 for windows software. Test of equality of proportion and t-tests were performed to test the significance of difference between percentage and mean values of lifestyle related variables, respectively. Logistic regression analysis was used to evaluate the maximum odds ratios (ORs) of the prevalence of MetS. Multiple logistic regression analyses were performed to estimate the age adjusted ORs using lifestyle related variables as covariates. Further, multiple logistic regression analysis

was performed to find out the maximum odds of MetS after adjusting for significant lifestyle related variables. Level of significance was considered at $p < 0.05$.

RESULTS

Table 1 depicts the prevalence of MetS of the study participants. Irrespective of sex and total sample, significantly higher ($z = 3.79, 2.92$ and 4.76 respectively for males, females and total sample, $p < 0.05$) prevalence of metabolic syndrome has been noticed in case of urban study participants than that in case of rural participants. Considering urban habitat, markedly high prevalence of metabolic syndrome is found among males (43.75%), females (47.47%) and also in total sample (45.64%). Fact remains that the prevalence of metabolic syndrome is found to be alarmingly high among the rural females (27.27%), too.

Table 2 shows the mean and percentage values of different lifestyle related variables. Significant rural-urban differences are evident for almost all the quantitative and qualitative variables, irrespective of sex.

Table 3 shows the prevalence of MetS according to education, occupation and media exposure status by sex and total sample. It is evident that participants with lower level of education have lower prevalence of MetS. As expected, sedentary jobholders show significantly higher prevalence of MetS than those with non-sedentary jobs in males, females and in total sample ($z = 2.96, 10.47$ and 4.11 , respectively, $p < 0.01$). Considering both males and females, more than 30% of the sedentary jobholders are shown to have MetS. Irrespective of sex, participants exposed to mass media, show significantly higher prevalence of MetS compared to their media non-exposed counterparts. Media exposed females show a prevalence of 45.56% as against 34.62% for the male media exposed participants.

Table 4 depicts the prevalence of MetS according to activity level. As expected, irrespective of sex, less active participants show significantly higher prevalence (34.55% for males, 41.57% for females) of MetS compared to more active participants (16.35% for males, 28.00% for females) ($z = 3.13, p < 0.01$ for males; $z = 2.06, p < 0.05$ for females). Similar trend has also been noticed in case of total sample ($z = 3.40, p < 0.01$).

Table 5 shows the prevalence of MetS according to substance use. It is evident from the table, that irrespective of sex, smokers and smokeless tobacco users show lower prevalence of MetS, and the difference between these two groups in each sex is not statistically significant. On the other hand, prevalence of MetS is found to be significantly higher in the alcohol drinker group compared to non-drinker group for males, females and total sample, while the difference is significant in females ($z = 2.90, p < 0.01$) and in total sample ($z = 2.26, p < 0.05$). While drinker females have a prevalence of 46.08%, non-drinker females show a prevalence of 26.60%.

Table 6 depicts the result of multiple logistic regression analysis using lifestyle related variable adjusted MetS as dependent and adiposity related variables as independent variable. Only abdomen circumference was found to predict MetS significantly (Wald 4.737 with expB 0.951 95% CI = 0.908 – 0.995).

Table 1. Prevalence of MetS, by sex and habitat group

Trait	Male (%)		Female (%)		Total (%)	
	Urban (n = 96)	Rural (n = 94)	z (df = 1)	Urban (n = 99)	Rural (n = 88)	z (df = 1)
MetS	43.75	19.15	3.79*	47.47	27.27	2.92*
				45.64	23.08	4.76*

* Significant at < 0.01 level.

DISCUSSION AND CONCLUSION

In the developing nations, including India, the forces of modernization play an important role in changing the lifestyle of the people. Availability of high fat rich food and accessibility to low cost vehicle are simultaneously affecting the health of the individuals in accumulating excess body fat, specifically at the central region of the body. This eventually increases the risk of certain CVD risk factors and MetS.

The present study portrayed a very high prevalence of MetS among the Bhutias, an ethnic group residing in the Himalayan State of Sikkim. Previously, in a different set of Bhutias, the present authors studied the MetS epidemiology (Mukhopadhyay and Sarkar 2018), where females showed a significantly higher prevalence of MetS which corroborates with the present study and the study among the US (Freiberg et al. 2004). On the other hand, higher prevalence of MetS among the males has been found elsewhere (Dallongeville et al. 2005).

It has been observed that the female study participants are mostly housewives and usually spend most of their times in doing household works. Bhutias were fond of fat and fiber rich food items like *chhurpi* (product made from buffalo milk), beef, pork and so on. Frequent consumption of fast food available in the market was also evident among them. Again, the energy expenditure was found to be very less due to availability of low cost transportation. This double effect of high fat rich food and less energy expenditure accumulates fat in their body and gradually harms their cardio-metabolic health. It can be intuitively stated that the transition from a rural traditional lifestyle to an urbanized modern lifestyle leads to a substantial change in socioeconomic and demographic changes. That in turn may change education level, occupational status and income level of the population. The changes in these attributes can have influence on dietary habits, behaviors and physical activity level that in turn affects the MetS.

Adjusted multiple logistic regression analysis showed the importance of central obesity in predicting MetS than overall obesity measured by BMI and bioelectrical impedance. Present study has uniquely found abdomen circumference as the most significant predictor of MetS,

even after adjustment for significant lifestyle related variables. Abdomen circumference as a significant predictor of different CVD risk factors was shown in a previous study among the Bhutias of Sikkim (Sarkar 2013). The central adiposity by means of abdomen circumference might be of interest in future in predicting chronic illnesses like CVD, MetS, diabetes, dyslipidaemia and so on.

ACKNOWLEDGMENTS

Authors are grateful to the study participants for their cooperation to conduct the study successfully. Indian Statistical Institute is acknowledged for financial and other logistic supports.

Chapter 246

BISEXUAL DIFFERENCES IN THE ASSOCIATION OF ADIPOSITY MEASURES WITH THE RISK OF HYPERTENSION AMONG THE TRIBES OF GUJARAT, INDIA

Gautam K. Kshatriya*

Department of Anthropology, University of Delhi, Delhi, India

INTRODUCTION

Obesity is a global epidemic health issue which is leading to several health problems like hypertension, diabetes, cardiovascular diseases (CVDs) and metabolic abnormalities (WHO, 2000; Amin, Fatima, Islam & Gilani, 2015). Increased urbanization and modernization has led to sedentary lifestyle belonging to all the age groups living in urban as well as rural parts of India (Yusuf, Reddy, Ôunpuu & Anand, 2001, WHO, 2008, Bansal et al., 2012, Kshatriya & Acharya, 2016). It has been reported that change in dietary and physical activity patterns are often the result of environmental and societal changes associated with development and lack of supportive policies in health, agriculture, transport, urban planning, food processing and education (WHO, 2016). According to ‘A Global Brief on Hypertension’ (WHO, 2013), about one million people around the world are affected by hypertension which causes strokes, heart attacks, kidney failure and other fatal conditions. Globally, complications out of increased blood pressure accounts for 9.4 million deaths every year (WHO, 2009; Lim et al., 2012). Furthermore, undetected high blood pressure has dangerous consequences which often lead to life-threatening complications (WHO, 2013).

It may be added here that hypertension is directly responsible for 57% of all stroke deaths and 24% of all coronary heart disease deaths in India (Anchala et al., 2014). Studies revealed that prevalence of hypertension in urban India is about 29-45% in males and 25-38% in females (Gupta et al., 2003; Gupta & Gupta, 2009). Obesity has long been established as an

* Corresponding Author's Email: g26_51@yahoo.co.in.

important and independent risk factor for the development and complication of hypertension (Misra, 2000; Hossain, Kavar & El Nahas, 2007; Redón et al., 2008; Park et al., 2013; WHO, 2013; 2016; Moraes, Lacerda, Moreno, Horta & Carvalho, 2014; Rizwan et al., 2014; Hall, Do Carmo, Da Silva, Wang & Hall, 2015; Jiang, Lu, Zong, Ruan & Lin, 2016; Kshatriya & Acharya, 2016). Body Mass Index (BMI), Waist Circumference (WC), Waist-to-height ratio (WHtR) and Waist-hip ratio (WHR) are simple and valid anthropometric measures for the assessment of obesity and risk of hypertension (Mello et al., 2011; Rodea- Montero, Evia-Viscarra & Apolinar-Jiménez, 2014; Zhang et al., 2017). WC has stronger positive association with elevated blood pressure (Yalcin, Sahin & Yalcin, 2005). Nyamdorj et al. (2008) found the association of the development of hypertension with BMI as strong as that with central obesity indicators in Mauritian Indian and Mauritian Creole. Body composition measures such as visceral fat (VF) and percent body fat (PBF) are also considered to be significant indicators of body fat distribution in association with hypertension risk found in populations with different ethnicities worldwide (Després et al., 2000; Gupta 2004; Lam, Koh, Chen, Wong & Fallows, 2015; Pereira et al., 2015). Asian Indians have higher abdominal body fat storage even at a lower BMI, and are susceptible to a higher risk of CVDs and metabolic syndrome (Chandalia, Abate, Garg, Stray-Gundersen & Grundy, 1999; Raji, Seely, Arky & Simonson, 2001; Raji et al., 2004; Forouhi, 2005; Bhat et al., 2005; Misra & Shrivastava 2013). Also, abdominal obesity leads to elevated blood pressure and insulin resistance (Poirier et al., 2005). Obese individuals with accumulated visceral fat have an increased risk for hypertension, type 2 diabetes mellitus and other cardiovascular events (Bidulescu et al., 2013) and variation in fat distribution mediates cardiometabolic risk factors (Neeland et al., 2012).

Several studies have reported the prevalence of hypertension in adults (Gupta & Mehrishi, 1997; Gupta, 2004; Thankappan et al., 2005; Kaur et al., 2007; Kaur et al., 2012; Rizwan et al., 2014; Panda et al., 2017) and children in urban areas of India (Mohan et al., 2003; Singh, 2007; Durrani & Fatima, 2011; Shetty, Shetty, Sasidharan & Shenoy, 2013; Singh et al., 2013; Kumar et al., 2017). Studies (Gerber, Schwartz, Schnall & Pickering, 1995; Dua & Kapoor, 2000) have shown sex differences in association of adiposity measures with blood pressure in urban populations. WHR, WHtR and conicity index (CI) are found to be higher in females due to the gynoid pattern of fat distribution (Mungreiphy et al., 2012). It has been found that males are more prone to abdominal fat deposition in comparison to females, which is responsible for higher central adiposity in them (Despres et al., 2000). Sex-wise studies on hypertension have highlighted that systolic blood pressure (SBP) levels increases with advancing age (Reddy, 1998; Raina, Chander, Prasher & Raina, 2016) and the increase has been reported to be more prominent in females than males (Dua, Bhuker, Sharma, Dhall & Kapoor, 2014; Raina et al., 2016).

Obesity and its association with elevated blood pressure has been reported among tribal populations of India (NNMB, 2009; Kapoor, Saluja, Verma & Kapoor, 2012; Kshatriya & Acharya, 2016). Meshram et al. (2012) found that the risk of hypertension was significantly higher among overweight/obese tribal men and women as compared to normal individuals. Similarly, Kapoor et al. (2012) reported a positive correlation of BMI and mid upper arm circumference (MUAC) and a negative correlation of PBF with risk of hypertension among tribal communities from different regions of India. Similar studies among tribes across varied ecological settings within India have observed association of hypertension with anthropometric indices (Babu, Kusuma & Naidu, 1996; Kusuma, Babu & Naidu, 2002;

Mukhopadhyay & Mukhopadhyay, 2001; Kerketta, Bulliyya, Babu, Mohapatra & Nayak, 2009; Maken & Verte, 2016). The nomadic tribal groups of Rajasthan have shown an increased hypertensive tendency at elevated abdominal and visceral fat adiposity as well (Sachdev, 2011). BMI and abdominal adiposity showed positive correlation with hypertension in tribal population of India (Kshatriya, 2014). However, to the best of our knowledge there is hardly any study on the association of adiposity measures with blood pressure among the tribal population groups of India. Therefore, the present study is an attempt to investigate the bisexual variations in the association of adiposity measures with the risk of hypertension among the three tribal populations namely Dhodia, Kukna and Choudhuri of Gujarat, India for a better understanding of correlates of hypertension among these socially and economically deprived populations.

MATERIALS AND METHODS

Ethical Statement

Prior ethical clearance to conduct the research was obtained from the Institutional Review Committee, Department of Anthropology, University of Delhi. Informed written consent from each participant was obtained prior to the actual commencement of the study.

Area and People

The present study was conducted among three tribes namely Dhodia, Kukna and Choudhuri from Valsad and Surat districts of Gujarat, during August-September 2013 (Figure 1).

Source: <https://www.mapsofindia.com/maps/gujarat/>.

Figure 1. Geographical location of the selected districts in Gujarat.

The tribes of Gujarat are agriculturalists and have a sedentary life. They are also involved in other occupations such as government jobs, cattle rearing and manual labour. All the studied tribes have access to basic amenities such as water, electricity, education and healthcare. Ways of modern entertainments such as television, radio and music systems,

mobile phones are making their way into the life of these tribal communities replacing the traditional community activities such as folk singing, narrations and dancing. Prevalence of alcohol consumption was low in the tribes of Gujarat.

Sampling Method and Sample Size

A total of 30 villages from two districts namely Valsad and Surat of Gujarat were chosen on the basis of the residence in acculturated areas of development (areas where development activities have reached). These areas have comparatively closed access to “urban centers.” House listing was prepared for these selected villages. Subsequently, the age and sex composition of adult men and women was prepared for the studied three tribes from the house listing. A sample size of 120 adult men and 120 adult women from each of the three tribes was selected using simple random sampling. As a result, the study comprised of a total of 721 participants out of which 360 were men and 361 were women aged 20-60 years.

Exclusion criteria: People with any type of growth and developmental disorders, severe health issues in the past year, and the existence of any secondary cause of hypertension were not included in the current study. People who were hesitant about being part of the study were also excluded.

Data Collection and Measurements

Two trained anthropologists guided by the principal investigator constituted the field research team for data collection. To avoid any measurement of entry biases, one person was assigned the responsibility of taking all the measurements while the other used to enter data into the datasheet. Same set of instruments were used throughout for recording the measurements.

A structured format was used to collect demographic information such as name, age, sex, name of tribe from each of the participants.

Standard techniques were followed while taking all the anthropometric measurements (Lohman, Roche & Martorell, 1988). The standing height was measured to the nearest of 0.1 cm using a movable anthropometer. Skinfold thicknesses at four sites (biceps, triceps, sub-scapular and supra-iliac) were estimated using the Holtain’s skinfold thickness calliper and sum of four skinfolds (SF_4) was measured.

Percent body fat (PBF) and visceral fat (VF) were estimated by bioelectrical impedance analysis (BIA) using Omron Karada Scan Body Composition Monitor (Omron Health Care Co., Kyoto, Japan), which is a hand-held impedance analyser. Each participant’s particulars such as height, age and sex were recorded into the instrument after which the participant was instructed to stand on the platform with their feet placed on the scales present at the platform, the hand-held monitor was then held by them which scanned the body and gave recording of the impedance and body fat percentage calculation. The participants were encouraged to remove their shoes and heavy clothing before taking measurements. Weight was also recorded to the nearest 0.1kg with the help of this instrument.

Mid upper arm circumference (MUA), minimum waist circumference (MWC) and maximum hip circumference (MHC) were recorded using non-expandable measuring tape. Waist hip ratio (WHR) and waist height ratio (WHtR) were also estimated.

Blood pressure was measured following American Heart Association (AHA) guidelines (Liz, 2005). The systolic and diastolic blood pressure was measured using a standard mercury sphygmomanometer on the left upper arm of the participants in the sitting position. A minimum 15-minute rest before the measurement and a 5-minute interval between two consecutive measurements were ensured. The average of two readings was recorded.

Individual Classification

High body mass index (BMI) has been treated as a strong indicator of obesity and hypertension in various populations. Furthermore, the “obesity paradox” has been reported which indicated that low BMI was associated with hypertension (Hainer & Aldhoon-Hainerová, 2013). Therefore, we considered both low and high BMI statuses as predictors of hypertension risks. According to the World Health Organization (WHO) guidelines for Asian populations, individuals with BMI $<18.5 \text{ kg/m}^2$ were considered as underweight; $\geq 18.5 \text{ kg/m}^2$ but $<23 \text{ kg/m}^2$ as normal; $\geq 23 \text{ kg/m}^2$ but $<27.5 \text{ kg/m}^2$ as overweight and $\geq 27.5 \text{ kg/m}^2$ as obese (WHO, 1998; Kesavachandran, Bihari & Mathur, 2012). In the present study, we have combined the overweight and obese categories as the proportion for each of the two was found to be very low.

Several studies have demonstrated that WHtR is more closely associated with central obesity, encompassing the adjustment to various statures (Hsieh, Yoshinaga, Muto, Sakurai & Kosaka, 2000; Lin et al., 2002; Sayeed et al., 2003) and overcoming the negative correlation of height to metabolic syndromes (Henriksson, Kindblom, Agren, Nilsson-Ehle & Rastam, 2001). The mean height of Indian tribes is less than the mean height of the general Indian population (Gautam & Adak, 2006). Therefore, WHtR can be an ideal obesity measure and a strong indicator of health (Ashwell & Hsieh, 2005) in Indian tribal populations. In the present study, WHtR was classified into two categories: (1) <0.50 as normal (Peng et al., 2013); and (2) ≥ 0.50 as at risk for both males and females. MWC and WHR have also been associated with central obesity and cut-offs also vary sex-wise because of the differences in the deposition of fat in males and females. In case of minimum waist circumference (MWC), males with $<90 \text{ cm}$ and females with $<80 \text{ cm}$ were considered as normal, while males with $\geq 90 \text{ cm}$ and females with $\geq 80 \text{ cm}$ were considered as at-risk category (Alberti, Zimmet & Shaw, 2006; WHO, 2011). WHR was classified into two categories: 1) males with <0.90 and females with <0.85 as normal, and (2) males with ≥ 0.90 and females with ≥ 0.85 as at-risk category (WHO, 2011).

The 7th Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure cut off have been used for classifying the participants as normal, prehypertensive and hypertensive (Chobanian et al., 2003). Participants with SBP $<120 \text{ mm Hg}$ and DBP $<80 \text{ mm Hg}$ were recorded as normal, while those with SBP between 120 and 139 mm Hg or DBP between 80 and 89 mm Hg were classified as prehypertensive. Participants with blood pressure $\geq 140/90 \text{ mm Hg}$ were considered hypertensive (James, 2014).

Statistical Analysis

Data entry was done in Microsoft Excel 2007, and further analyses were carried out using SPSS version 16.0 for Windows (SPSS Inc., Chicago, Illinois, USA). Descriptive statistics, such as mean and standard deviation (SD), were estimated for the selected anthropometric, body composition and physiometric variables. Student's t-test was performed to estimate the level of significance between the two sexes. Pearson's correlation coefficient was estimated for anthropometric, body composition measures and blood pressure. Furthermore, linear regression for total population as well as for males and females separately was used by taking SBP and DBP as dependent variables and MWC, MUAC, WHR, WHtR, BMI, SF₄, PBF and VF as independent variables. Data were cross tabulated by adiposity variables and sex, and analysed by using three-dimensional contingency chi-square test.

RESULTS

Table 1 describes the characteristics of the studied tribal populations of Gujarat. The mean values of height, weight, minimum waist circumference (MWC), mid upper arm circumference (MUAC), visceral fat (VF), waist hip ratio (WHR) and waist height ratio (WHtR) were observed to be higher in males as compared to females. The mean difference between males and females were found to be statistically significant.

Mean values of diastolic blood pressure (DBP), percent body fat (PBF) and sum of four skinfolds (SF₄) were found to be higher among females than males. Variables like PBF, DBP and SF₄ were found to be statistically significant between the two sexes.

Table 2 shows the partial correlation between adiposity variables (MWC, MUAC, BMI, WHR, WHtR, PBF, VF and SF₄) and physiometric variables (SBP and DBP) among the selected tribal groups of Gujarat. Findings indicate a significant positive correlation of all the adiposity measures with the physiometric variables.

Table 3 presents the linear regression analysis of physiometric measures with anthropometric and body composition measures as independent variables for the tribes of Gujarat. It can be seen that SBP and DBP have a significant positive impact on MWC (β -0.42, adj. R²-0.08; β -0.61; adj. R²-0.06) and PBF (β -0.14, adj. R²-0.04; β - 0.16; adj. R²-0.07) among the selected populations of Gujarat.

Table 4 shows sex-wise linear regression analysis for anthropometric and body composition measures with SBP and DBP as the dependent variables. It can be seen that among females, SBP has a significant positive impact on MWC (β -0.42; adj. R²-0.11) and PBF (β -0.21; adj. R²-0.09) while, DBP was found to have significant positive effect on MWC (β - 0.59; adj. R²-0.08), PBF (β -0.16; adj. R²-0.07) and VF (β - 0.38; adj. R²-0.09). However, in case of males, SBP and DBP had significant positive impact only on MWC (β -0.38; adj. R²-0.10; β - 0.68; adj. R²-0.18).

Further, a mutually independent hypothesis and a number of partially independent hypotheses were tested for various categories of blood pressure (normal, PHTN and HTN), normal and at risk anthropometric variables and sex using three-dimensional chi-square analysis. In partially independent hypothesis, we tested: (a) sex as independent of blood pressure and normal and at risk anthropometric variables, (b) blood pressure as independent

of sex, and normal and at risk anthropometric variables, and (c) normal and at risk anthropometric variables as independent of sex and blood pressure.

Tables 5, 6, 7 and 8 present the distribution of normal and at-risk categories of MWC, WHR, WHtR, BMI, and blood pressure by sex among the selected tribal groups of Gujarat. Our initial analysis showed that normal and at risk anthropometric variables, by sex and blood pressure were not mutually independent, which led us to test for partial independence. In partial independence, three of the one variable was tested as independent of the other two. It was found that except for BMI, all the chi-square tests for partial independence were statistically significant at $p < 0.05$. Thus, it can be inferred that adiposity measures and risk of hypertension by sex are strongly associated.

DISCUSSION

The findings of the studied tribal communities of Gujarat showed that there are significant sex differences in several anthropometric measurements and blood pressure among the tribal populations. In addition, these groups also showed the risk of hypertension along with the burden of malnutrition (underweight and overweight). It may be noted here that obesity co-exists with underweight in India and hence, the country suffers from a double burden of malnutrition (Popkins, 2002; Kshatriya & Acharya, 2016). The development of obesity involves the amalgamation of numerous social, behavioural, cultural, physiological, metabolic and genetic factors (National Research Council [NRC], 1989; WHO, 2016). WHO (2011) reported the estimated prevalence for hypertension among the Indian National population as 32.5%, which was found to be higher than the estimated prevalence of 22.5%

among tribal populations. Increasing trend of hypertension among tribal populations was also observed in various studies (NNMB, 2009; Naidu, Nayak & Sadi, 2016; Rizwan et al., 2014; Kshatriya & Acharya, 2016). Kshatriya & Acharya (2016) reported that hypertension was observed to be higher among females as compared to males in tribal populations of India. Only few studies (Deshmukh, Gupta, Dongre & Bharambe, 2006; Chockalingam et al., 2005; Ghosh, 2007; Gupta et al., 2007; Kapoor et al., 2012; Singh et al., 2013) have been carried out on the factors determining hypertension risk among Indian people. However, to the best of our knowledge this is the first attempt to find out the bisexual differences in the association of adiposity variables with blood pressure among the tribal populations of Gujarat.

Men in the studied tribal groups had significantly higher mean height, weight, MWC, MUAC, VF, WHR and WHtR, while mean values of DBP, PBF and SF₄ were significantly higher among females, indicating sexual differences in adiposity measures. Various studies have shown that adiposity measures play a significant role in predicting hypertension risk among males and females (Yalcin, 2005; Ghosh, Mukhopadhyay & Barik, 2016; Kandpal, Sachdeva & Saraswathy, 2016; Kshatriya & Acharya, 2016). Pal et al. (2014) found that rural Bengalee females had significantly higher PBF and fat mass while males had central adiposity resulting in higher mean values of anthropometric measures such as MWC, WHR and WHtR. Significant sex differences were also observed in numerous studies conducted on urban population groups residing in India (Sanjeev, Indech, Jit & Johnston, 1991; Bhadra, Mukhopadhyay & Bose, 2002; Deshmukh et al., 2006). However, few studies (Kapoor, Kapoor & Durnin, 1999; Misra et al., 2001; Mungreiphy & Kapoor, 2010; Bansal et al., 2012) have reported higher percentage of females to be overweight than males and have higher mean for WHR, WHtR and BMI due to relatively more gynoidal pattern of fat distribution. Furthermore, significant positive correlations between adiposity measures (MWC, MUAC, PBF, BMI, VF, WHR, WHtR, SF₄) and physiometric variables (SBP and DBP) were also obtained. A strong positive correlation between BMI, WHR, MWC, WHtR and SBP and DBP was observed in many studies as well (Deshmukh et al., 2006; Gupta et al., 2007; Chakraborty, Bose & Bisai, 2009; Pal, De, Sengupta, Maity & Dhara, 2014).

The regression analysis indicates that SBP and DBP have a significant positive impact on MWC and PBF among the selected population groups. Sex-wise regression analysis indicated that among females SBP had a significant positive impact on MWC and PBF, while DBP had a significant impact on MWC, PBF and VF; while in case of males, SBP and DBP had significant positive impact only on MWC, which could be because men are prone to abdominal fat deposition in comparison to women (Deprés, 2000; Mungreiphy et al., 2012). Similar results have also been reported in a few studies earlier (Ghosh et al., 2016; Kandpal et al., 2016; Kshatriya & Acharya, 2016).

It was also attempted in the present study to find out the association of normal and risk categories of adiposity markers such as MWC, WHR, WHtR and BMI with blood pressure levels (normal, PHTN and HTN) among both the sexes of selected tribal groups using three-dimensional contingency chi-square analysis. A mutually independent hypothesis along with various partially independent hypotheses were tested to investigate the association of adiposity measures with risk of hypertension by sex. Bisexual differences were found to be statistically significant for MWC, WHR and WHtR and various categories of blood pressure. Mutual dependence was also reported between sex, anthropometric measures and blood pressure. Kshatriya & Acharya (2016) in their study reported that tribal women above 40 years of age are at a greater risk of suffering from undernutrition because of the social and

gender disparities faced by them leading to chronic health conditions. Low BMI and undernutrition was reported to be a risk factor for CVD (Pal et al., 2014; Kshatriya & Acharya, 2016). An increased visceral fat mass is responsible for greater blood pressure due to activation of several mechanisms such as leptin resistance, insulin resistance and inflammation (Sniderman, Bhopal, Prabhakaran, Sarrafzadegan & Tchernof, 2007). Tainget al. (2016) also found MWC and WHtR to be strongly associated with blood pressure than BMI. People belonging to Asian ethnicities have a high total body fat and a greater amount of abdominal and visceral fat at a given BMI in comparison to other ethnic groups (Lear et al., 2007; Misra & Shrivastava, 2013). Therefore, anthropometric measures (MWC, WHR and WHtR) which take into consideration central fat distribution may be more helpful in determining the adverse health conditions in various communities in India.

Differences in blood pressure between various ethnic groups have been observed in India and various studies suggest that numerous factors are associated with SBP and DBP in rural as well as urban population. Higher SBP and DBP are associated with malnutrition, inaccessible health services, alcohol consumptions and smoking in rural groups (Reddy, Rao & Reddy, 2002; Hazarika, Narain, Biswas, Kalita & Mahanta, 2004; Kusuma & Das, 2008; Kshatriya & Acharya, 2016), whereas sedentary lifestyle, unhealthy food habits, stress are being associated with high blood pressure levels in urban areas (Mungreiphy & Kapoor, 2010; Ibrahim & Damasceno, 2012; WHO, 2013). The tribal groups practicing farming have been reported for elevated risk of hypertension than those occupied in other occupations probably because of the unsatisfactory yield of crops leading to greater economic crisis and stress (Wasnik & Jawarkar, 2016).

Finally, the sex-wise differences and association of adiposity markers with hypertension observed in the current study will be helpful in extending these results to other tribal population groups for developing effective intervention strategies.

CONCLUSION

The findings of the present study show an increasing prevalence of prehypertension and hypertension among both the sexes in tribal areas at an alarming rate. The sex-wise differences and association of adiposity markers with hypertension in the current study would be helpful in designing better health care delivery systems in the areas of tribal concentration.

ACKNOWLEDGMENTS

The help rendered by Prof. Satwanti Kapoor, University of Delhi and Dr. Arnab Ghosh, Visva Bharati, Santi Niketan in formulation of the research problem is greatly appreciated. We express our gratitude to Subhendu Kumar Acharya, Miss Hemlata and Mr. Gajanan for participating in data collection. We sincerely acknowledge the support and co-operation of the participants of the selected villages. This study was funded to GKK by the Indian Council of Medical Research (ICMR), Government of India, bearing project reference number 5/4/8-2/2010 NCD-II.

CONFLICT OF INTEREST

The author reports no conflicts of interest.

INTRODUCTION

Hypertension or raised blood pressure is one of the important components of metabolic syndrome (Grundy et al., 2004). It is one of the major risk factors for cardiovascular diseases and affects one billion people in worldwide, leading to heart attacks and strokes (WHO, 2013). It is considered a major global public-health challenge because of its high frequency and has concomitant risks of cardiovascular and kidney diseases (Oyewole and Oritogun, 2012). The incidence and prevalence of hypertension continues to increase around the world (Chen and Lipscombe 2008; Karen et al., 2008). Globally, cardiovascular diseases account for approximately 17 million deaths a year, nearly one third of the reported total deaths (WHO, 2008). Of these, complications of hypertension account for 9.4 million deaths worldwide every year (Lim et al., 2012). Hypertension is one of the leading reported causes of death in Bangladesh and approximately 17,000 or 2.28% of total deaths is due to hypertensive problem as reported by World Health Organization (WHO) in 2014 (WHO, 2014).

The prevalence of pre-hypertension and hypertension in different countries, particularly among university students was reported for Saudi Arabian females at 13.5% (Koura et al., 2012), West Bank 27.1% (male 38% and female 11.2%) (Tayem et al., 2012), Malaysia 42.9% (Lee et al., 2010), and Kuwait 39.5% (Al-Majed and Sadek, 2012). Among medical students, 67% presented with pre-hypertension and hypertension (Kulkarni et al., 2011) in India, 12.8% in Chile (Palomo et al., 2006) and 6.9% to 24.9% in Portugal (Dores et al., 2010). Once hypertension is identified, the patients should be regularly checked for their blood pressure (BP), in order to monitor and maintain the blood pressure under control (Black and Hawks, 2005). Gender, age, parental history of hypertension, and behavioral factors, like body mass index(BMI), sleep duration, smoking status have all been identified as the risk factors in hypertension (Tadesse and Alemu, 2014).

Many studies have been carried out on hypertension among university students in Western countries (Tayem et al., 2012; Simão et al., 2008; Hujova 2013; Soliman et al., 2014). While in Bangladesh researchers have investigated the association between hypertension and socio-economic and demographic factors among patients and in the general population (Rahman et al., 2015; Yinon et al., 2013). University students need to be considered a valuable asset for any nation; thus, special attention should be paid to them because of their potential influence on their families and their contribution to the nation's workforce in the future. Thus, it is important to determine the prevalence of hypertension and pre-hypertension among university students and to investigate the relationship between high

blood pressure and socio demographic factors such as gender, residence, smoking, parents' history of hypertension, body mass index, religion, number of family members, parents' education, family income, sleeping duration and physical activities, in order to determine possible corrective measures.

Therefore, the aim of this study was to investigate the prevalence and associated factors of hypertension among university students in Bangladesh.

METHODS

Data

The cross-sectional study sample consisted of 911 (727 males and 184 females) university students. Data were collected from Rajshahi University, Bangladesh. Students were interviewed from January to June 2014. The age range of the subject's was 18-27 years old at the time of measurement. Rajshahi University was selected because it is the second largest university in Bangladesh, having a student population of nearly 25,000 students at any particular time. These students come from different parts of the country. Data were collected using a semi-structured pre- and post-tested questionnaire containing pre-coded and open-ended questions. Body height was measured as the distance from the top of the head in the midsagittal plane to the floor and body weight was taken while wearing thin clothing using an electronic weighing machine [Digital Display Height and Weight Tester (sgsport.en.alibaba.com)]. Body mass index was calculated as the ratio of weight in kilograms divided by the square of height in meters. i.e., $BMI = \text{weight (kg)} / (\text{height(m)})^2$. BMI was categorized into four groups as follows: underweight, $BMI \leq 18.5$; normal weight, $18.5 < BMI < 25$; overweight, $25 \leq BMI < 30$; and obese, $BMI \geq 30$ (Hossain et al., 2012).

Outcome Variable

Blood pressure (BP) was considered as an outcome variable. Systolic blood pressure (SBP) and diastolic blood pressure (DBP) were taken from each subject three times in the sitting position using mercury sphygmomanometers (Pickering et al., 2005), and the average value was taken for the analysis. Each subject was allowed to rest 5 minutes between measurements, and without having any drinks or smoking. The sample was classified into four classes according the range of blood pressure (BP); (i) Hypotension ($SBP < 90\text{mmHg}$ or $DBP < 60\text{mmHg}$), (ii) Normal ($90 \leq SBP < 120\text{mmHg}$ and $60 \leq DBP < 80\text{mmHg}$), (iii) Pre-hypertension ($120 \leq SBP < 140$ or $80 \leq DBP < 90\text{ mmHg}$), and (iv) Hypertension ($SBP \geq 140\text{ mmHg}$ or $DBP \geq 90\text{mmHg}$) (Tadesse and Alemu, 2014).

Independent Variables

In this study, we attempted to establish the relationship between hypertension and some of the selected risk factors. The possible predictors for hypertension of university students were selected based on the published studies of university students in other countries (Tayem et al., 2012; Simão et al., 2008; Hujova, 2013; Soliman et al., 2014). Gender was classified as male (code 1) and female (code 2), permanent residence, was classified into two groups; rural (code 1) and urban (code 2), cigarette smoking behavior was divided into two groups; non

smoker (no, code 0) and smoker (yes, code 1). Fathers' and mothers' education, were classified into four levels; uneducated (code 0), primary education (code 1), secondary education (code 2) and high education (code 3). Fathers' occupation was classified into three groups; agriculture (code 1), service (code 2) and business (code 3). Mothers' occupation was categorized into two groups; housewife (code 1) and non housewife (code 2). On the basis of the parents' history of hypertension the sample was categorized into two groups; parents' with hypertension, yes (code 1) and no (code 0). Body size was classified into three groups; underweight (code 1), normal (code 2) and overweight or obese (code 3), the subjects' religion was divided into two groups; Non-Muslim (code 0) and Muslim (code 1), family members were set up as ≤ 4 persons (code 1), 5-7 persons (code 2) and ≥ 8 persons (code 3). Parents' family income was divided into three groups; monthly income < Taka 10000 (code 1), 10000-20000 Taka (code 2) and $\geq$ Taka 20000 (code 3). Sleeping hours a night of the subjects was classified into two classes; <7 hours (code 1) and ≥ 7 hours (code 2), and finally, physical activity with 45 minutes a day on at least five days a week, was divided into two groups; no (code 0) and yes (code 1).

Sample Size Determination and Sampling

Since our target population is known (approximately 25000; male 20000 and female 5000), thus the significant sample size for this study would be calculated on the basis of population size, and the following formula was used for determining the sample size:

$$n = \frac{N}{1 + Nd^2}$$
 where, n = required sample size, N = population size (in here 25000), d = marginal error (we used, d = 0.032), lastly, a 95% confidence level was utilized (Rana et al., 2015). The formula provided the minimal sample size of 900 for this study. However, a total of 930 selected students were asked by one of our coauthors, using a standard questionnaire, to report their socio-demographic characteristics. Nineteen (female 12 and male 7) students who did not agree to provide their information were excluded from the current analysis. Consequently, 911 students were included in this study.

The population was considered heterogeneous, divided into two different groups (male and female). However, they were considered homogeneous within the groups. A two-stage stratified random sampling technique with a proportional allocation was used for selecting the samples from Rajshahi University. The proportional allocation technique indicated that 727 males and 184 female students would be needed for this study.

Statistical Analysis

The prevalence of each category of BP was determined using by frequency distributions. The Chi-square test was utilized to find the association between the categories of BP and some of the selected socio-economic, demographic, anthropometric and behavioral factors. Finally, multinomial logistic regression analysis was used to find the effect of socio-economic, demographic and behavioral factors on pre-hypertension and hypertension of university students. Data were analyzed using the Statistical Package for Social Sciences (SPSS, IBM version 20). A value of $p < 0.05$ was regarded as statistically significant in the analysis.

RESULTS

Background Information

A total of 911 university students were interviewed and examined. Among them 727 (79.8%) students were male and 184 (20.2%) were female. The age of the subjects varied from 18 to 27 years, with a mean age of 22.27 ± 1.86 years. The present study demonstrated that the prevalence of pre-hypertension and hypertension among university students were 42.50% and 25.60% respectively, while the prevalence of hypotension among university students was very low (1.50%) (Figure 1). Students with hypotension were excluded from further statistical analysis.

Three categories; normal, pre-hypertension and hypertension were considered in the further statistical analysis.

Association between Hypertension and Other Selected Variables

The Chi-square test (χ^2 -test) was used to find the association between the blood pressure categories (BPC) and various socio-economic, demographic, anthropometric and behavioral factors among the university students in Bangladesh. In this study, gender ($p < 0.001$), residence ($p < 0.05$), cigarette smoking behavior ($p < 0.05$), body mass index ($p < 0.001$), parents' education level ($p < 0.05$), fathers' occupation BPC ($p < 0.01$), family income ($p < 0.05$), sleeping duration a night ($p < 0.05$) and physical activity ($p < 0.01$) were significantly associated factors of university students' BPC.

Factors Influencing Hypertension in University Students

Blood pressure (BP) category was our dependent variable, and it was three categories (i) normal (ii) hypertension and (iii) hypertension, the multinomial logistic regression model was selected to find the effect of socio-economic, demographic and behavior factors on pre-hypertension and hypertension, normal BP was considered as reference case. Only the significant associated factors got from the χ^2 -test were considered as independent variable of multinomial logistic model (Table 2). The coefficients and adjusted odds ratio (AOR) of multinomial logistic regression model demonstrated that male students were more likely to get pre-hypertension [AOR = 5.80, 95% CI, 3.67-9.16; $p < 0.01$] and hypertension [AOR = 26.90, 95% CI, 11.41-63.45; $p < 0.01$] than female students. Students slept less than 7 hours a night who was more prone to get pre-hypertension [AOR = 0.65, 95% CI, 0.46-0.92; $p < 0.05$] and hypertension [AOR = 0.67, 95% CI, 0.45-0.95; $p < 0.05$] compared with who slept ≥ 7 hours. Over-weight or obese students had higher chance in developing pre-hypertension and hypertension than those who were under-weight [AOR = 0.15, 95% CI, 0.06-0.41; $p < 0.01$] and [AOR = 0.03, 95% CI, 0.01-0.11; $p < 0.01$], and those of normal weight [AOR = 0.45, 95% CI, 0.18-0.90; $p < 0.05$] and [AOR = 0.19, 95% CI, 0.07-0.47; $p < 0.05$] students, respectively. Students performed a certain level of physical activity with 45 minutes a day on at least five days a week who was less likely to get hypertension [AOR = 2.38, 95% CI, 1.12-5.04; $p < 0.01$] than their counterparts (Table 2).

DISCUSSION

This study was aimed at assessing the prevalence and associated factors of pre-hypertension and hypertension among university students in Bangladesh. A total of 911 students from 7 residence halls at Rajshahi University were recruited using a simple random sampling strategy. The study duration was conducted from January to June, 2014. The cross-sectional study identified pre-hypertension and hypertension as a significant health problem among these university students aged 18-27 years. The present study demonstrated that more than one-third and near to one-fourth of the students were pre-hypertensive and hypertensive respectively of the students was pre-hypertensive. University students are young adults who are more likely to be in a pre-hypertension mode rather than displaying full hypertension. The category of pre-hypertension was created to alert people to their risk of developing high blood pressure (HBP) so they could make the necessary lifestyle changes that may avoid the development of hypertension. If the students could be induced to change to their lifestyle and food habits this may help in avoiding the development of high blood pressure and therefore avoiding hypertension in their life in the future.

Hypertension among university students in Bangladesh was identified as lower than in other developing countries such as the university students in Gambia (38.0%) (Van der Sande et al., 2000), Tunisia (35.1%) (Hajer et al., 2012) and Ethiopia (28.3%) (Awoke et al., 2012). However, the hypertension of Bangladeshi university students was higher than in some other countries such as in Nigeria (19.3%) (Isezuo et al., 2011), Kuwait (7%) (Al-Majed and Sadek, 2012) and Saudi Arabia (9.3%) (Ibrahim et al., 2014). The present study demonstrated that male students were more likely to get hypertension compared to female students, and our

results agree with the findings of studies in Kuwait (Al-Majed and Sadek, 2012), Tunisia (Awoke et al., 2012), Hungary (Katona et al., 2011), Qatar (Bener et al., 2004) and USA (Everett and Zajaacova, 2015). In this study, we observed that the prevalence of risk factors such as overweight or obese and cigarette smoking behavior among male students was higher than that of female students, while more number of female students (19.4%) performed physical activities than male (8.9%), these were the important reasons for gender differentiation in hypertension. Same causes were found in one of the USA studies, they also found young men were less likely to be aware of their hypertensive status compared to young women (Everett and Zajaacova, 2015).

It is also important to note that overweight or obese students were at higher risk of getting hypertension compared to underweight and normal weight students. This finding supports previous reports from Tunisia, Portugal, and sub-Saharan African countries (Tadesse and Alemu, 2014). A study conducted in sub-Saharan countries showed that blood pressure was associated with BMI (Tasfaye et al., 2007). A study in Tunisia also demonstrated this relationship between BMI and hypertension (Hajer et al., 2012). Physical activities can reduce body fat, and it is suggested as a significant lifestyle modification that may help in the prevention of hypertension. It was noted that only 11.1% Rajshahi university students performed physical activity with 45 minutes a day on at least five days a week, also observed that university students who performed physical activities was less likely to get hypertension. Same result had been found in other studies (Diaz and Shimbo, 2013; Kokkinos et al., 2009). It was found that habitual short sleep duration at night was an important risk cause for hypertension (Calhoun and Harding, 2010). This study also demonstrated that students who slept less than 7 hours at night had a higher probability of getting hypertension than their counterparts. It is thought that over time, a lack of sleep can damage human body's ability to regulate stress hormones, leading to hypertension, sleep can help to control human blood pressure and helps nervous system remain healthy. The duration of sleep at night seven to eight hours may play a role in the treatment and prevention of high blood pressure.

Limitation of the Study

Only students staying in the residence halls of Rajshahi University were involved in this study; therefore, the present data cannot reflect the prevalence of hypertension among university students in Bangladesh as a whole. This study should not be limited to only university students but must involve other young adults of the same age range, especially those who may have dropped out from school/college and are working. During the study, some students were not willing to freely give information about BP, while others agreed but gave incorrect information especially regarding their parents' income and social status, so these students had to be excluded. This study was conducted as preliminary work to investigate the prevalence of pre-hypertension and hypertension and its association with selected anthropometric measures, socio-demographic and behavior factors. However, it was not possible to look at other important factors that may also be directly related to hypertension, such as diabetes mellitus, alcohol consumption (Tadesse and Alemu, 2014), environmental factors (Simão et al., 2008), and sedentary lifestyle (Tayem et al., 2012). Clearly, more studies of this type are required.

CONCLUSION

The purpose of this study was to investigate the prevalence and associated factors of pre-hypertension and hypertension among Rajshahi University students in Bangladesh. The study showed that gender, residence, cigarette smoking behavior, BMI, parents' education, fathers' occupation, family income, duration of sleep a night and physical activities were significantly associated with categories of blood pressure among university students. Multinomial logistic regression exhibited that male students, less than 7 hours sleep in night and overweight or obese students were more likely to become pre-hypertensive and hypertension compared to their counterparts. It is also observed that a student did not perform a certain level of physical activity at least 45 minutes in a day (at least 5 days in a week) who was more likely to get hypertension than his/her counterpart.

The findings of this study have policy implications as well as leading to recommendations that would be helpful to health authorities and policy makers to lead to substantial improvements in the area of hypertension and public health. It would especially assist the government and other policy makers to take the proper initiatives to promote the awareness among young adults about the dangers of becoming hypertensive in Bangladesh and to begin to take steps to attempt to reduce the prevalence of hypertension. Government and non-government organization need to have awareness and provide the necessary counseling regarding the risks of overweight and obesity among university students. Physical activities is a most important predictors of hypertension, and it can help to reduce the body fat. The health authorities of Bangladesh government and university authorities should take initiative to ensure that all university students must perform exercise at least 45 minutes for at least 5 days in a week.

Additional Points

Availability of Data and Materials

Primary data was used in this study and data was collected from university students in Bangladesh. Many variables were collected from subjects. The dataset will be used for other propose, we do not wish to share our data.

Ethical Approval

This study obtained the permission from the authority of the University of Rajshahi, and the research has been approved by the ethical committee of the *institute of Biological Science (IBSC), Rajshahi University, Bangladesh*.

Consent

Written consent was taken from each participant after a detailed oral explanation about the study. We got consent from all subjects for publishing their data.

Disclosure

There was no grant, technical or corporate support for this research project.

Conflicts of Interest

All authors declared that there were no conflicts of interests in relation to this study.

Authors' Contributions

Golam Hossain and Sadekur Rahman designed the study, wrote the proposal, collected the data, analyzed the data and wrote the manuscript. Suhaili Mohd, Rashidul Alam Mahumud and Pete E. Lestrel approved the proposal and revised the manuscript.

ACKNOWLEDGMENT

We appreciate the authority of Students' Residence Hall, University of Rajshahi, Bangladesh for giving permission to take data from students.

Chapter 248

INCREASING INCIDENCE OF MACROSOMIA: THE IMPACT OF MATERNAL SOMATIC AND BEHAVIORAL PARAMETERS ON NEWBORN WEIGHT STATUS

Sylvia Kirchengast*, PhD

Department of Anthropology, University of Vienna, Vienna, Austria

INTRODUCTION

The prevalence of obesity and the so called “syndrome x” has increased drastically worldwide during the last 20 years. Consequently, many authors already warn of global epidemics (Ford & Mokard 2008, Rheeder 2006). 10 years ago, the number of obese people on earth exceeded the number of people suffering from starvation and malnutrition for the first time in the long history of *Homo sapiens* (FAO 2008). Currently more than 1.9 billion adults, 18 years and older, are overweight and more than 600 million are obese (WHO 2016). Obesity is commonly defined, as a level of adiposity that is sufficiently excessive to damage health, demonstrated by an increased risk of metabolic and cardiovascular diseases, such as diabetes, hypertension, stroke and some forms of cancer (Danaei et al. 2009). The clustering of metabolic symptoms, in particular insulin resistance, dyslipidemia (with hypertriglyceridaemia and low levels of high density lipoprotein cholesterol) and cardiovascular symptoms such as hypertension are called “syndrome x”, which is significantly related to obesity (Reaven 1988, Dwyer et al. 2002). The most severe expression of syndrome x is found in combination with central obesity and is often referred as the metabolic syndrome. To determine obesity commonly the body mass index (BMI) based on body weight and height (kilograms per square meter) is used. (WHO 1995). The World Health Organization (WHO) defines overweight as a BMI above 25.00kg/m², while a BMI above 30.00kg/m² is an indicator of obesity. A BMI above 40.00kg/m² is seen as morbidly

* Corresponding Author's Email: sylvia.kirchengast@univie.ac.at.

obese (WHO 1995). These cut offs are defined for adults. Obesity however, is not only a problem of the adult population, currently overweight or obesity affects one in ten children or adolescents worldwide (WHO 2016). In Europe, one in five children can be classified as overweight or obese (WHO 2016). Since sub adult individuals are still growing, and the growth patterns differ according to sex, the use of BMI cutoffs for determining obesity is problematic among sub adults. Therefore, BMI percentiles for each separate sex and age class are widely used for the determination of overweight and obesity among children and adolescents (Wang & Wang 2000).

The strong association between obesity and the risk of several chronic diseases such as heart disease, stroke, hypertension, but also pancreatitis, osteoarthritis and cancer makes the high rates of obesity among children as well as adults to a major concern of public health (Kulie et al. 2011, WHO 2016). This is especially true of the association between obesity and insulin resistance. Insulin resistance or type II diabetes is one of the most serious metabolic diseases with disastrous long term consequences such as blindness, nephropathy or the amputation of the lower extremities. The past president of the American Diabetes association, Francine Kaufman pointed out exceptionally strong interaction between obesity and type II diabetes and introduced the term “diabesity” (Kaufmann 2005). There is no doubt that obesity and insulin resistance but also syndrome x represent a global health crisis that threatens the economies worldwide (Hu 2011). Consequently the prevention of obesity as well as syndrome x is the major goal of public health strategies. In order to develop strategies to reduce the risk of developing obesity and syndrome x, it is necessary to analyze the potential risk factors. During the last decade several potential risk factors of syndrome x have been identified. It is well documented, that beside genetic factors life style patterns such as hyper alimentation and physical inactivity have a significant impact on the development of obesity and syndrome x. The life style factors promoting syndrome x can be seen in a close context with westernized life style patterns and modernization (Fall 2001, Harell et al. 2015).

OBESITY, SYNDROME X AND NEWBORN SIZE

Recently there is growing interest in the association between newborn size and the risk of obesity, and syndrome x in later life (Ramadhani et al. 2006). Newborn size, mainly expressed by birth weight, reflects intrauterine growth patterns, which are determined by genetic factors but also intrauterine environment. Obesity and insulin resistance during later life are more common among small for gestational age newborns (SGA) but also among large for gestational age newborn (LGA) (Ramadhani et al. 2006, Hermann et al. 2010, Wang et al. 2009, Bamberg et al. 2013, Yu et al. 2015).

During the 1980s and the early 1990s the British epidemiologists Barker and Hales proposed the concept that environmental stress factors such as malnutrition in utero, might influence the development of obesity and syndrome x later on in life (Barker & Clark 1997; Barker 1999). According to Barkers so called thrifty phenotype hypothesis fetal undernutrition and therefore fetal programming are the causative factors a of later life metabolic diseases (Barker 1999, Robert & Woods 2014). In utero nutritional deficiencies lead to small for gestational age newborns who respond to their low level of nutritional intake in early life through alterations in growth and metabolism which increase the risk of obesity

and syndrome x in later life (Barker 1999). According to Barker and Hales hypothesis small for gestational age newborns have metabolically thrifty mechanisms for fat storage and glucose sparing with reduced rates of glucose oxidation in insulin-sensitive target tissues (Barker 1999). Consequently, low birth weight, which has been defined as a birth weight below 2500g regardless of gestational age, is on the one hand one of the strongest single risk factors for early neonatal mortality and morbidity (Mahumud et al. 2017). On the other hand low birth weight is also an important risk factor for developing obesity and syndrome x in later life. This association is of special concern because according to the World Health Organization (WHO) the prevalence of low birth weight is 15.5% globally and 96.5% of low birth weight infants are born in developing countries (Mahumud et al. 2017).

MACROSOMIA

As pointed out above birth weight as a predictor of health in later life showed a u-shaped curve with both low birth weight as well as high birth weight associated with increased risks. High birth weight or large for gestational age newborn is commonly called macrosomia, which defined a birth weight above 4000g or 4500g (Dennedy & Dunne 2013). The American College of Obstetricians and Gynecologists supports the use of a 4500g cutoff, irrespective of gestational age because a birth weight of more than 4500g increases the risk of adverse maternal and perinatal outcome (ACOG 2000). Unfortunately for the definition of macrosomia the cut offs of 4000g and 4500g are still used simultaneously. Another definition of macrosomia is a birth weight greater than 90% for gestational age after correcting for neonatal sex and ethnicity. Ye et al. (2015) plead for a population specific definition of macrosomia and suggested a cut-off of 4500g for African and Latin American newborn but a cut off of 4000g for Asian populations. Based on these, definitions macrosomia affects 1 to 10% of pregnancies worldwide. As to be expected the prevalence of macrosomia (birth weight above 4000g) widely from a low of 0.5% in India to a high of 14.9% in Algeria (Koyanagi et al., 2013). In Western countries macrosomia (> 4000g) is encountered in up to 10% of deliveries (Campbell 2014). In the United States approximately 7% of newborn had birth weight above 4000g, 1% had birth weight higher than 4,500g, and 0.1% had birth weight higher than 5000g (Dennedy & Dunne 2013).

Using the definition of fetal macrosomia as a neonate with a birth weight above 4.5 kg the prevalence of macrosomia ranges from 1.3 – 1.5% of all births in developed countries. Only few neonates are extremely large. According to the Guinness world record the heaviest infant born to a healthy mother, weighing 10.2kg was born in Italy in 1955. Few other infants weighing more than 6kg are recorded such as a newborn weighing 7kg from Cambria, UK in 1992, and an infant weighing 7.6kg in Bahia Brazil in 2005. In 2007, a newborn weighing 6.6kg was born in Cancun Mexico. In China, an infant weighing 6.2kg was born 2006 and in 2008, a Chinese baby weighing 5.5kg was delivered. The largest baby ever recorded in Bangladesh was born in 2008 weighing 6kg (Sultana et al. 2007). Without any doubt such extraordinary heavy newborn are extremely rare. What we can observe however are changes in mean birth weight. A secular trend in birth weight was observable in some countries from the mid to the late 20th century (Bralic et al. 2006; Oken 2013, Begic et al. 2016, Chegeni et al. 2016). In Moscow, Russia, for instance, the mean birth weight of boys increased from

3450g in 1987 to 3500g in 2002, among girl mean birth weight increased from 3360g to 3450g (Treyak et al. 2005). In Sweden, the mean weight at birth increased from 3596g to 3631g during the period 1992 and 2002 (Surkan et al. 2005). Furthermore, the prevalence of macrosome newborns ($> 4500\text{g}$) increased from 3.7% to 4.6% during this period (Surkan et al. 2005).

According to popular press and public perceptions birth weight seems to increase steadily during the last decades, but this is not true. Recent data indicate that in developed countries the mean birth weight has begun to decline. In the United States the incidence of low weight newborn ($< 2500\text{g}$) increased, while the prevalence of newborn weighing more than 5000g decreased. (Oken 2013). Similar trends are observed for France and Australia (Oken 2013). In Austria the prevalence of macrosome newborn ($> 4500\text{g}$) decreased from 7.1% in 2006 to 6.4% in 2016. (Statistik Austria 2017) These trends may be due to changes in population mixture but mainly due to changes in obstetric practice. Induction of labor, but also increased monitoring of diabetic and prediabetic women during pregnancy account for this decrease in macrosome newborn.

This reduction of macrosomia is of special importance because macrosomia increases maternal as well as newborn morbidity and mortality. Higher stillbirth rates but also higher fetal mortality rates are associated with a birth weight above 4250g in non-diabetic mothers and with a birth weight above 4000g among diabetic mothers (Mondestin et al. 2002, Najafian & Cheraghi 2012). Furthermore, macrosomia increases birth complication in particular the risk of shoulder dystocia and trauma to the birth canal, bladder, perineum and anal sphincter (Campbell 2014). This is especially true of birth weights higher than 4500 g and particularly among birth weight, which exceeds 5000 g. Consequently, fetal macrosomia is associated with increased risks for emergency Cesarean section (CS) and instrumental delivery (Campbell 2014). For the newborn macrosomia associated complications, include beside increased mortality, brachial plexus or facial nerve injuries, fractures of the humerus or clavicle and birth asphyxia (Campbell 2014)

Consequently, macrosomia is clearly associated with birth complications and maternal as well as newborn morbidity and mortality (Najafian & Cheraghi 2012, Campbell 2014). Additionally, many studies have shown that macrosomia is a risk factor for obesity and syndrome x in later life (Yu et al. 2008, Hermann et al. 2010). Therefore, the analysis of potential risk factors of macrosomia is essential.

Factors strongly associated with fetal macrosomia include genetics, ethnic factors, duration of gestation, presence of gestational diabetes, and maternal diabetes mellitus types I and II (Li et al. 2014, Kamana et al. 2015). It is well documented, that maternal diabetes-pregestational as well as gestational diabetes - is one of the strongest risk factors associated with macrosomia (Hammoud et al. 2013). Furthermore, maternal prepregnancy weight status affects birthweight (Pözlberger et al. 2017). Obese women but also women experiencing excessive gestational weight gain are more likely to give birth to larger infants (Kirchengast & Hartmann 2018). Additionally some studies plead for an association between macrosomia and multiparity as well as older maternal age (Li et al. 2015). An important fetal factor is sex. Male infants are heavier than female ones at any gestational age and the prevalence of macrosomia is higher among male newborns.

As mentioned above beside the perinatal complications, macrosomia represents an important risk factor of syndrome x and obesity in later life (Herrmann 2010). Therefore, the analysis of potential risk factor of macrosomia despite of maternal diabetes is of special

importance. In the present study, the impact of fetal sex but also maternal prepregnancy weight status and maternal behavior on newborn size was tested among more than 10 000 term births in Vienna, Austria.

MATERIAL AND METHODS

Data Set

This retrospective study is based on a data set of 10231 singleton births, which took place at the University Clinic of Gynecology and Obstetrics in Vienna, Austria between 1995 and 2000. Although, a total of 18425 births were collected, only 10231 met the strict inclusion and exclusion criteria. Following inclusion criterions have been defined:

1. Births between the 38th and 41th week of gestation, because only term births should be included in analyses to make maternal pregnancy weight gain and newborn anthropometric data more comparable.
2. Only pregnant women ageing between 18 and 45 years were enrolled in the present study whose first prenatal check took place during the eighth week of gestation.
3. All prenatal check-ups of the mother-child passport were completed.
4. Delivery of a single infant without congenital malformations
5. No registered maternal diseases before and during pregnancy i.e., no hypertension (BP < 150/90 mmHg), no preeclampsia, no protein or glucose in the urine, no pregnancy related immunization.

Additionally the following exclusion criteria have been defined:

1. Early Teenage pregnancy i.e., maternal age below sixteen years.
2. Coincident medical diseases such as diabetes mellitus or nephropathy.
3. Drug or alcohol abuse.
4. Twin birth or IVF.

Gestational age was calculated in terms of the number of weeks from the beginning of the last menstrual bleeding to the date of delivery (= duration of amenorrhoea). All subjects originated from Austrian or central Europe.

Maternal Parameters

All 10231 women enrolled in the present study aged between 17 and 49 years (mean = 25.3 yrs SD = 5.7). The following maternal somatometric parameters were determined at the first prenatal visit: Stature height was measured to the nearest 0.5cm and prepregnancy weight (PPW), was measured to the nearest 0.1kg on a balance beam scale. Additionally maternal weight at the end of pregnancy (EPW) was measured before birth. The weight gain during pregnancy (PWG) was calculated by subtraction of pre-pregnancy weight from body weight

at the end of pregnancy. Maternal weight status before pregnancy was described by means of the body mass index (BMI) (kg/m^2). Weight status was classified according to the recommendations of the WHO (1995).

- < 18.50 = underweight
- 18.50 - 24.99 = normal weight
- 25.00 - 29.99 = overweight
- 30.00 - 39.99 = obese
- > 40.00 = morbid obese

Newborn Parameters

Birth weight, birth length, head circumference, diameter fronto-occipitalis and acromial circumference were taken directly from newborn immediately after birth. Newborn weight status was defined as follows: low < 2500g, normal 2500 - 3999g, high 4000 - 4500g and macrosome > 4500g (Dennedy & Dunne 2013). Furthermore, the one- and the five minute APGAR scores (Casey et al. 2001) for the evaluation of the newborn were determined.

Mode of Delivery

Spontaneous vaginal birth and caesarean section were recorded. Caesarean sections requested by the mother without any medical indication were not carried out at this hospital.

Statistical Analyses

Statistical analyses were performed by means of SPSS for Windows program Version 22.0. After calculating descriptive statistics (means, SDs), group differences were tested regarding their statistical significance using Duncan analyses. Furthermore, χ^2 analyses and odds ratios were computed. Multiple regression analyses were performed to test the impact of maternal prepregnancy BMI, stature height, gestational weight gain on birth weight. Additionally binary logistic regressions were computed in order to test the association between maternal parameters and newborn weight status. Normal birthweight was coded as 1, high birth weight and macrosomia were coded as 2.

RESULTS

Sample Description

Altogether 10231 newborns have been enrolled in the present study. The number of male newborn ($n = 5249$; 51.3%) surpassed the number of female ones ($n = 4991$; 48.7%). The majority of mothers (73.3%) corresponded to the WHO definition of normalweight. 8.9 % of

the mothers were classified as underweight because their prepregnancy body mass index was below 18.50 kg/m². 14.2% of the mothers were classified as overweight (BMI 25.00 to 29.99kg/m²) and only 3.6% corresponded to the definition of obesity i.e., a prepregnancy BMI above 30.00 kg/m². Only 0.3% of the mothers were classified as morbidly obese (BMI > 40.00 kg/m²). The mean weight gestational gain was 12.9kg (SD = 5.5) ranging from 2 to 38 kg. The majority of mothers were nonsmokers before pregnancy (64.2%) and during pregnancy (72.0%). 22.8% of the mothers were classified as heavy smokers (> 10 cigarettes per day) before pregnancy and 7.6% of the mothers were still heavy smokers (>10 cigarettes per day) during pregnancy.

The Prevalence of High Birth Weight and Macrosomia

As to be expected the majority of newborn (90.3%) corresponded to the definition of normal weight (2500 - 3999g). 1.8% of the newborn were classified as low weight (< 2500g). 7.3% corresponded to the definition of high birthweight (4000 - 4499g) and only 0.8% corresponded to the definition of macrosomia (> 4500g). Male and female newborn differed significantly in weight status ($p < 0.0001$). The prevalence of high birthweight and macrosomia was significantly higher among male newborn. 9.5% of the male newborn showed a birth weight between 4000 and 4500g, 0.7% were heavier than 4500g. Among female newborn the prevalence of high birth weight was only 4.9% and only 0.2% of the female newborn were classified as macrosome.

As demonstrated in Table 1, high weight newborn and macrosome newborn were not only heavier than their normal weight and low weight counterparts, they were also significantly longer and exhibited significantly larger head dimensions and significantly higher acromial circumferences. Concerning vital parameters, however it turned out the one minute and five minute appear scores of high weight and macrosome newborn were only slightly decreased in comparison to their normal weight counterparts.

The Impact of Maternal Parameters on Newborn Weight Status

Newborn weight status was significantly associated with various somatic but also behavioral parameters of the mothers. As demonstrated in Table 1 the mothers of high weight or macrosome newborn were significantly older, taller and heavier than the mothers of normal weight or low weight newborns. Furthermore, they exhibited significantly larger pelvic dimensions and experienced a significantly higher gestational weight gain ($p < 0.0001$). Maternal prepregnancy overweight and obesity increased the risk of giving birth to high weight and macrosome newborn significantly. While the prevalence of high weight and macrosome newborn was below 5% among underweight mothers and 6.9% among normal weight mothers, 12.3% of overweight women, 13.9% of obese women and 33.4% of morbidly obese women gave birth to high weight or macrosome offspring. Smoking before and during pregnancy reduced the risk to give birth to a macrosome newborn.

Table 1. Maternal and newborn characteristics according to newborn weight status

n	Birth weight categories				
	< 2500g	2500 - 3999g	4000 - 4500g	> 4500g	.

**Table 2. Impact of maternal characteristics on newborn size.
Multiple regression analyses**

	R ²	B	Sig	95% CI
Dependent variable. Newborn weight				
Maternal age	0.28	4.59	< 0.001	2.42 – 6.77
Stature height		12.77	< 0.001	10.91 – 14.62
Prepregnancy BMI		25.37	< 0.001	22.19 – 28.54
Gestational weight gain		17.38	< 0.001	15.14 – 19.62
Newborn sex		- 126.4	< 0.001	-150.15 - -102.61
Prepregnancy nicotine consumption		- 2.96	< 0.001	- 4.57 - - 1.34
Nicotine consumption during pregnancy		- 8.53	< 0.001	- 11.07 - - 5.99

These findings were corroborated by the results of the multiple and the binary logistic regression analyses (see Tables 2 and 3). Maternal age, stature height, prepregnancy weight status and gestational weight gain were significantly positively associated with birth weight and macrosomia. Nicotine consumption before and during pregnancy were significantly

negatively associated with birth weight however only insignificantly negatively with macrosomia.

**Table 3. Impact of maternal characteristics on macrosomia.
Multiple regression analyses**

	Exp (B)	Sig	95% CI
Dependent variable: newborn weight status

Prepregnancy nicotine consumption	0.99	0.646	0.94 – 1.04
Nicotine consumption during pregnancy	0.95	0.267	0.86 – 1.04

Newborn Weight Status and Delivery Mode

Delivery mode differed significantly according to newborn weight status (Chi-square = 24.8; $p < 0.0001$). Caesarean section rate of the whole sample was 21.5%. The lowest cesarean section rate was found among normal weight newborn (21.1%) the highest rate among low weight newborn (37.0%). High weight newborn (4000 - 4399g) and macrosome newborn (> 4500 g) showed a CS rate of 23.0% and 23.6% respectively. High birth weight (OR = 1.12 CI 0.93 - 1.32) and macrosomia (OR = 1.16, CI 0.62 - 2.15) increased slightly the risk to give birth via caesarean section in comparison to normal weight newborn.

DISCUSSION

Macrosomia is clearly an important risk factor of obesity and syndrome x during childhood and adult life (Yu et al. 2008, Wang et al. 2009, Hermann et al. 2010). Large for gestational age infants show distinctly different growth patterns from normal weight newborns during childhood. They experience higher weight gains and show significantly higher body mass indices than their normal weight counterparts (Yu et al. 2008, Bocca-Tjeertes et al. 2014). These high rates of obesity increase the risk of metabolic disorders from early childhood onwards (Bocca-Tjeertens et al. 2014). Therefore, the analysis of factors promoting macrosomia is of special importance. In the present study, the impact of fetal sex but also maternal somatometric factors as well as maternal behavioral factors on birth weight was analyzed. In detail a large sample of term births taking place in Vienna Austria were enrolled in the present analysis. Only 1.8% of the newborn were classified as low weight or small for gestational age (< 2500 g). This is much lower than the general prevalence of small for gestational age newborn in Austria (Statistik Austria 2016). Between 2007 and 2016 the rate of small for gestational age newborns ranges between 6.4 and 7.2%. This discrepancy is due to the fact, that exclusively term births have been included into the present study. The prevalence of high birth weight newborn (4000 - 4499g) was 7.3%. This rate is in accordance

with macrosomia rates ($> 4000\text{g}$) in other high-income countries (Campbell 2014). Only 0.8% of the newborn were heavier than 4500g. This low incidence of macrosomic newborn is comparable to that of the United States where about 1% of the newborn exhibit a birth weight above 4500g (Dennedy & Dunne 2013.) In the present study, fetal sex had a significant impact on macrosomia. The birth weight of 9.5% of the male newborn was between 4000 and 4500g, while only 4.9% of newborn girls were weighing between 4000 and 4500g and only 0.2% exhibited a birth weight above 4500g. These significant sex differences are in accordance with the results of several other studies. Male newborns typically weigh more than female newborns, in detail male newborns are generally approximately 150 - 200 g heavier than female newborn of the same gestational age near term (Kirchengast 2014). Furthermore, male newborn are more likely to be macrosomic than female ones (Di Renzo et al. 2007).

As to be expected, macrosome newborn were not only heavier they also were longer and had larger heads. This fact may be the main reason that caesarean section rates were significantly higher among mothers of macrosome newborns. In the present study, more than 23.0% of newborn weighing above 4500g were delivered via Caesarean section. This finding is in accordance with the results of numerous previous studies, which yielded significantly increased caesarean section rates among mothers of macrosome newborns (Barber et al. 2011, Kirchengast & Hartmann 2017)

Concerning maternal parameters, prepregnancy weight status was significantly associated with birth weight. While less than 7% of normal weight mothers gave birth to a newborn heavier than 4000g, this was true of more than 12% of overweight mothers, nearly 14% of obese mothers and more than 33% of morbidly obese mothers ($\text{BMI} > 40.00\text{kg/m}^2$). Maternal obesity is general seen as a main risk factor of newborn macrosomia (lit.). Additionally mothers of high birth weight (4000 - 4499g) and macrosome newborns ($> 4500\text{g}$) are taller and experienced a higher gestational weight gain than mothers of low weight and normal weight newborns. These findings corroborate the results of several previous study (Clausen et al. 2005, Pözlberger et al. 2017). Furthermore, the pelvic dimensions of mothers of high weight and macrosome newborns are larger than those of mothers of normal weight or low weight newborn. These increased pelvic dimensions may enable mothers of large fetuses to experience vaginal delivery despite of the large dimensions of the fetus.

Concerning maternal behavioral factors, the impact of nicotine consumption before and during pregnancy on newborn size was tested. Smoking before and during pregnancy increased the risk of giving birth to a small for gestational age newborn, but reduced the risk of giving birth to a macrosome one smoking however, should not be used to reduce the risk of macrosomia.

Macrosomia and associated obesity and syndrome x during later life are important issues of public health and obstetrics but these association patterns are also of interest from view point of evolutionary biology. Of course, it is not the task of evolutionary biology and/or evolutionary anthropology to develop new treatment strategies, but they may focus on the evolutionary basis of the prevalence of macrosomia on the one hand and the association between macrosomia and later life health issues on the hand. Evolution is the central paradigm in biological science and consequently Theodosius Dobzhansky stated “*Nothing in biology makes sense except in the light of evolution*” (Dobzhansky 1973). From this point of view, macrosomia and associated health risks in later life have to be considered, within the framework of human evolution.

The first hazard of an evolutionary analysis of macrosomia and associated health risks is that we have no information regarding newborn size and birth weight of our hominid ancestors. Only few fossil remains of hominid infants are known, for example the Neanderthal neonates from Mezmaiskaya 1 (Russia) and Le Moustier 2 (France) (Weaver et al. 2016). These rare skeletal remains allow us to reconstruct birth patterns among Neanderthals (Ponce de Leon et al. 2008), but we have no information regarding mean birth weights among different hominid species. The analysis of birth weight among our hominid ancestors is quite difficult. Wells (2009) used maternal height as predictor of birth weight and reconstructed birth weight trends from the Paleolithic onwards. According to Wells analyses birth weight declined from about 3500 to 3300 g during Paleolithic to about 2900 to 3000g during Neolithic times. Consequently, the transition from the Paleolithic hunter-gatherer subsistence to Neolithic agriculture was associated with a decrease of birth weight but also a deterioration of health. Nevertheless, we cannot assume that macrosomia was a common condition during Paleolithic times. The typical life style of our Paleolithic ancestors was characterized by a high level of physical activity because high levels in daily activity in search of food, water and sleeping sites were necessary. Diets consisted to a high degree of vegetable food, protein (50 to 80%) and a low fat content (Konner and Eaton 2010). It can be assumed, that typical non-communicable diseases such as hypertension, heart disease, cancer, diabetes or obesity have been rare or rather unknown during Paleolithic times (Lieberman 2003). The Neolithic transition changed the lifestyle of our ancestors drastically (Larsen 1995). The adoption of agriculture and animal husbandry allowed the production of a surplus of food and consequently population growth. Our ancestors developed semi-permanent settlements and gave up their mobile lifestyle. Dietary breadth declined dramatically and diet consisted of high carbohydrate crops such as rice, barley or wheat and tuber such as potatoes (Larsen 1995). Analyses of Neolithic skeletal remains indicate protein deficiencies and periodic food shortages. Furthermore, domestication of animals and plants changed the environments dramatically. The close proximity to domesticated animals exposed humans to a variety of new pathogens resulting in an increased frequency of infectious diseases (Armelagos et al. 1991). The use of feces as fertilizer and the construction of irrigation increased the contact with parasites. Many of these diseases had an important impact on early life. On the one hand, birth weight declined and this trend increased the risk of infectious diseases and increased infant mortality. On the other hand, maternal stature decreased during Neolithic transition and smaller birth size may be interpreted as an adaptation to this maternal somatic change (Wells 2009).

Birth weight increased again in recent times. The increase of macrosomia, which is evident for the last fifty years, can be interpreted as result of increasing affluence in developed but also developing countries. Rapid changes of our life style resulted in an obesogenic environment, which increased rates of obesity and type II diabetes but also gestational diabetes. Diabetes, first of all gestational diabetes are major risk factors for large for gestational age newborn (Kamana et al. 2015).

From an evolutionary viewpoint, increased rates of macrosomia in the second half of the 20th century may be an indicator of a mismatch between recent life circumstances and the environment in which our ancestors evolved. Modernization as well as urbanization took place, eating habits and physical workload changed dramatically. Especially a rapid transition in nutritional habits and general lifestyle increases the risk to be obese and to suffer from type II diabetes (Popkin 2003). This is especially true of rising economies in Asia. In 1980 less

than 1% of Chinese adults suffered from obesity and diabetes type II, in 2008 the prevalence had reached nearly 10% (WHO 2016). The prevalence of macrosomia (> 4000g) increased from 2.6% in the 1970s to 13.25 in the 1990s. Greatest increase occurred in urban areas. In Shanghai, the percentage of macrosomia increased by 50% from 1989 to 1999 (Yu et al. 2008).

Rapid modernization seems to enhance macrosomia rates. This is especially true of indigenous people experiencing rapid westernization. During the last 30 years, the incidence of macrosomia increased dramatically among indigenous populations in Canada. Among First Nations in Quebec and Ontario the a third of newborns is heavier than 4000g and a tenth is heavier than 4500g (Auger et al. 2013). Especially high rates of adult obesity and type II diabetes associated with westernization and modernization occur among Pacific Islanders (Jowitt 2014). The prevalence rates macrosomia (> 4500g) among Samoan mothers was 2.4%, while in developed countries less than 1% of the newborn are heavier than 4500g (Tsitas et al. 2015).

Macrosomia seems to be a problem of obesogenic environments, affluence and rapid modernization.

CONCLUSION

Macrosomia is strongly related to obesity and syndrome x in later life and have to be seen within the same context. Maternal obesity and high gestational weight gains enhance the risk of macrosomia independent of gestational diabetes. On the other hand macrosomia increases the risk of obesity and syndrome x.

INTRODUCTION

The concept of the metabolic disorder (MetD) has now been in existence for several years. The MetD also known as syndrome-X was first described by Gerald Reaven in 1988. It is mainly characterized by insulin resistance, hyperinsulinemia, hyperglycemia, dyslipidemia and arterial hypertension. The MetD is defined as glucose intolerance, impaired glucose tolerance (IGT) or diabetes mellitus, or insulin resistance together with two or more other components {e.g., Raised arterial pressure, i.e., $\geq 140/90$ mmHg; raised plasma triglyceride (≥ 150 mg/dl) and/or low HDL-C (< 35 mg/dl in men and < 39 mg/dl in women); central obesity, i.e., waist/hip ratio (WHR) > 0.90 in men and > 0.85 in women and/or body mass index (BMI) > 30.00 kg/m², micro-albuminuria, i.e., urinary albumin excretion rate ≥ 20 μ gm/minute or albumin/creatinine ratio ≥ 30 μ gm/mg} (Parikh and Mohan 2012; Awasthi et al. 2017; Ricci et al. 2017). The MetD can also be defined in terms of the associations between obesity, insulin resistance (IR), hypertension and dyslipidemia (NCEP 2001; Grundy et al. 2004; Furukawa et al. 2017). Some other study groups have suggested several other definitions of MetD {For example, The European Group for Study of Insulin Resistance (EGIR); American Association of Clinical Endocrinologists (AACE) and International Diabetes Federation (IDF)} (Yankey et al. 2017) (Table 1). The main cause of increase in MetD is observed to be the increasing prevalence of obesity in populations worldwide (Grundy 2016; Saltiel and Olefsky 2017).

Table 1. Different criteria for type-2 diabetes mellitus proposed by different organizations

Reference	Criteria for Type-2 Diabetes Mellitus (T2DM) or Non-Insulin Dependent Diabetes Mellitus (NIDDM)
WHO (1999)	Insulin resistance (glucose uptake in the euglycemic clamp below the lowest quartile for the general population) or impaired glucose regulation (impaired fasting glycemia, impaired glucose tolerance, or type-2 diabetes), with 2 or more of the following: 1) BP of 140/90 mm Hg or higher, 2) Triglyceride levels of 150 mg/dL (1.7 mmol/L) or higher and/or HDL-C levels less than 35 mg/dL (0.9 mmol/L) in men and less than 39 mg/dL (1.0 mmol/L) in women, 3) Waist-hip ratio >0.90 in men and >0.85 in women and/or Body mass index (BMI, calculated as weight in kilograms divided by the square of height in meters) greater ≥ 30.00 kg/m ²) and microalbuminuria.
NCEP (2001)	Insulin resistance and the presence of 3 or more of the following components: 1) Fasting plasma glucose concentration greater than 110 mg/dL (6.1 mmol/L), 2) Triglyceride concentration of 150 mg/dL (1.69 mmol/L) or greater, 3) HDL-C concentration less than 40 mg/dL (1.04 mmol/L) in men and less than 50 mg/dL (1.29 mmol/L) in women, 4) BP of 130/85 mm Hg or greater and 5), waist circumference (WC) greater than 102 cm in men and 88 cm in women.
NCEPATP3 (2005)	Presence of any three or more of the following: 1) Blood glucose greater than 5.6 mmol/L (100 mg/dl) or drug treatment for elevated blood glucose; 2) HDL cholesterol < 1.0 mmol/L (40 mg/dl) in men, < 1.3 mmol/L (50 mg/dl) in women or drug treatment for low HDL-C; 3) Blood triglycerides > 1.7 mmol/L (150 mg/dl) or drug treatment for elevated triglycerides; 4) Waist > 102 cm (men) or > 88 cm (women); 5) Blood pressure > 130/85 mmHg or drug treatment for hypertension.
International Diabetes Federation (IDF) (2006)	Presence of three or more of the five risk factors established by the American Heart Association/National Heart, Lung, and Blood Institute (AHA/NHLBI): 1) Abdominal obesity (WC ≥ 90 cm in men and ≥ 80 cm in women), 2) Hypertriglyceridemia (triglycerides ≥ 150 mg/dL or use of medications to lower triglycerides), 3) Low HDL-C.

Figure 1. Development of type-2 diabetes mellitus.

Type-2 diabetes mellitus (T2DM) comprises of different degrees of β -cell failure relative to varying degrees of insulin resistance (Cnop et al. 2005; Tripathi and Srivastava 2006). The T2DM, also known as non-insulin-dependent diabetes mellitus (NIDDM) is a chronic condition that affects the way of metabolizing glucose. In this condition the body either resists the effect of insulin on glucose or does not produce enough insulin that can metabolize glucose (Tripathi and Srivastava 2006) (Figure 1). The T2DM is described as the MetD of multiple aetiology which can be characterized by chronic hyperglycaemia with disturbances of carbohydrate, fat and protein metabolism resulting from the defects in insulin secretion, insulin action or both (Kharroubi and Darwish 2015; Heindel et al. 2017). In this case hepatic insulin resistance is the leading cause of the inability to suppress hepatic glucose production and peripheral glucose uptake impaired by peripheral insulin resistance. This combination gives rise to fasting and postprandial hyper-glycemia (Tripathi and Srivastava 2006). It is a

long-term disorder that affects other health problems in individuals. The T2DM mainly occurs due to excess body adiposity or obesity but some studies also observed the effect of genetics and environment in it. Environmental factors also have significant effect on the predisposition of T2DM and excess adiposity. It also increases the risk of other major problems like Cardio-Vascular disease (CVD) and coronary heart disease (CHD) in population.

RELATIONSHIP BETWEEN TYPE-2 DIABETES MELLITUS AND METABOLIC DISORDER

According to, National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III), traits of the MetD include an increased waist circumference (WC), blood pressure elevation, low HDL cholesterol, high triglycerides and hyperglycemia (NCEP 2001; Grundy 2004; Nsiah et al. 2015) (Table 1). When at least 3 of the 5 traits are present and affected individuals are insulin resistant then the condition is considered as MetD. Several studies have reported that MetD is a common problem among the individuals with T2DM. The presence of T2DM increases the risk of MetD to a great extent (NCEP 2001; Wilson et al. 2005) (Table 1). Studies have reported that obese individuals with high BMI and MetDs were also predisposed with T2DM (Meigs et al. 2006; Kautzky-Willer et al. 2016). Obesity contributes to the premature mortality and morbidities associated with MetD (Furukawa et al. 2017; Saltiel and Olefsky 2017) including preventable non-communicable diseases in population (WHO 2000; WHO Expert Consultation 2004; Deaton 2017) (Figure 2). The prevalence of obesity has exploded during the past two decades so the occurrence of MetD. Among the several MetDs (e.g., T2DM, hypertension, dyslipidaemia and CHD) insulin resistance is one of the most prevalent problem occurring due to obesity in developing countries (Ruderman et al. 2013; Misra and Bhardwaj 2014; Pozza and Isidori 2018). According to IDF (2013) report, global prevalence of T2DM in adults (20-79 years) was 8.3% (382 million people; 198 million men and 184 million women). The number is expected to rise beyond 592 million by 2035 with the global prevalence of 10.1%. In India, over 62 million individuals are diagnosed with T2DM and topped by 31.7 million in 2000 in the world with the highest number of people with T2DM followed by China (20.8 million) and United States (17.7 million) in second and third place, respectively (Joshi and Parikh 2007; Kumar et al. 2013).

Source: American Diabetes Association (1998, 2003).

Figure 2. The continuum of type-2 diabetes mellitus.

In the developed countries obesity and MetD (e.g., insulin resistance and CVD) have reached epidemic proportions (Berghofer et al. 2008; van Vliet-Ostaptchouk et al. 2014). Among the United States adults, the prevalence of obesity ($\text{BMI} \geq 30.00 \text{ kg/m}^2$) has increased from 15% in the early 1970s to the most recent estimate of 34% in 2009 – 2010 (Freedman 2011; Ogden et al. 2012; van Vliet-Ostaptchouk et al. 2014). Developing countries like India are experiencing rapid demographic, epidemiological and economic transitions (Subramanian et al. 2007; Prasad et al. 2010; Kapil and Sachdev 2012; Popkin et al. 2012; Mondal et al. 2017; Phua et al. 2017). These transitions are the main contributing factors for rapid increase in sedentary lifestyles, less physical work outs leading to increased adiposity levels. According to the preliminary National Family Health Survey (NFHS)–4 data, obesity prevalence rates have rapidly increased across India in the past 10 years bringing the national average prevalence to 20% for both women (20.8%) and men (19.9%) (McMurry et al. 2017).

The NFHS-3 study in India reported that 13% of women and 9% of men are overweight or obese. The prevalence of obesity is more pronounced among those living in the urban areas as compared to the rural areas (Laxmaiah et al. 2007; Subramanian et al. 2007; Yang et al. 2009; Sen et al. 2013; Varadharajan et al. 2013; Mondal et al. 2015, 2017; Ajayi et al. 2016). The prevalence of insulin resistance or T2DM is a major global health problem based on the Diabetes atlas (International Diabetic Federation 2009). India having over 20 million diabetic patients have become diabetic capital of the world (Khandelwal et al. 2017). About 80% of T2DM is preventable by changing diet, increasing physical activity and improving the living environment. However, because of lack of effective prevention and control programs, the occurrence of diabetes is likely to continue rising worldwide (Chatterjee et al. 2017; Perreault 2018). Therefore, there is an urgent need to focus on the problem associated with T2DM to reduce the relative burden of morbidity and mortality in population.

ROLE OF ANTHROPOMETRY IN ADIPOSITY ASSESSMENT AND METABOLIC DISORDERS

Anthropometry is a widely used non-invasive, in-expensive and easy-to-use technique to assess nutritional status, adiposity and body composition in both epidemiological and clinical settings in populations. Anthropometric indicators have been widely used {e.g., BMI, WC and WHR} to assess the body composition, nutritional status and excess adiposity in both epidemiological and clinical investigations. It is evident that the Asian populations have shown the greater prevalence of morbidity and mortality at lower levels of body mass index ($\text{BMI} = \text{weight/height, kg/m}^2$) and smaller WC values in adults (WHO, 2000; WHO Expert Consultation, 2004). Moreover, this BMI classification measures relative weight gain that has been directly related to health risks and morbidity patterns in different populations. BMI has been used extensively in most of the studies for evaluating excess adiposity patterns and overweight-obesity (Snehalatha et al. 2003; Mohan and Deepa 2007; Prasad et al. 2010; Sen et al. 2013; Sengupta et al. 2014; Girdhar et al. 2016). BMI relates weight to height and is the most widely used measure of body size and to estimate the prevalence of obesity within a population (WHO 1999; Khullar et al. 2014). BMI has been extensively used to assess body size but it does not account for the variation in body adiposity distribution and abdominal fat mass (WHO 1999; Wells and Fewtrell 2006). Excess abdominal adiposity is associated with

greater risk of obesity and obesity-related morbidity (Visscher et al. 2002; Després 2017) (Figure 3). The associations of T2DM and standard epidemiological translations of BMI and WC have been observed in adults (Alberti et al. 2007; Hsu et al. 2015) (Table 2). In terms of clinical perspective, central obesity (approximated by WC or WHR) provides more information than general BMI (Vazquez et al. 2007). Thus, measurements of WC and WHR are viewed as alternatives to BMI, with both measures regularly used in the clinical and research settings. WC has been shown to be the best simple measure of both intra-abdominal fat-mass and total adiposity (Barreira et al. 2014; Ashwell and Gibson 2016). Several studies have observed that WC alone reflects abdominal adiposity (Mohan and Deepa 2007; Barreira et al. 2014; Ashwell and Gibson 2016).

Table 2. Co-morbidity risks associated with suggested BMI and WC in Asian adults (WHO 2000)

Classification	BMI (kg/m ²)	Risk of co-morbidity (WC)	
		<90 cm (in men) <80 cm (in women)	≥90 cm (in men) ≥80 cm (in women)
Underweight	<18.50	Low but increased risk of other clinical problems	Average
Normal range	18.50-22.99	Average	Increased
Overweight	≥23.00		
At Risk	23.00-24.99	Increased	Moderate
Obesity I	25.00-29.99	Moderate	Severe
Obesity II	30.00	Severe	Very Severe

Figure 3. Factors affecting T2DM and Metabolic disorder.

In 1999, the WHO definition included a measure of obesity and defined obesity in terms of either BMI or WHR. WC in combination with BMI has been implemented in guidelines for the assessment and treatment of excess adiposity (obesity) related mortalities and morbidities (WHO 2000; Deurenberg-Yap et al. 2002; Mohan and Deepa 2007; Barreira et al. 2014; Ashwell and Gibson 2016). WHO (2000) has suggested co-morbidity risks associated with different levels of BMI with higher WC among Asian adults. Hence, WC has been advocated as a simple clinical alternative to BMI for detecting adults with possible health risks due to obesity (WHO 2000; WHO Expert Consultation 2004; Mohan and Deepa 2007;

Pratyush et al. 2012; Barreira et al. 2014; Ashwell and Gibson 2016). Abdominal obesity which is a condition due to increased amount of intra-abdominal fat including visceral adipose tissue (WHO 2000; Sullivan et al. 2015) is a major cause of T2DM. WC and WHR are useful indicators of abdominal obesity. Increased WC and WHR among the Asian populations reflect increased visceral adipose tissue and increased risks of MetDs (Deurenberg-Yap et al. 2002; Prasad et al. 2010; Soares and Müller 2017). Several studies have observed a higher percentage of body-fat, increased prevalence of metabolic risk factors at lower BMI levels among various Asian populations (Deurenberg-Yap et al. 2002; WHO 2004; Misra and Khurana 2011; Soares and Müller 2017). Increased prevalence of abdominal obesity in Asians as compared with those in Caucasians has also been reported (Deurenberg-Yap et al. 2002; Wang et al. 2005; Mohan and Deepa 2007; Misra and Khurana 2011). Hence, abdominal obesity assessed using WC is considered to be more appropriate to predict MetDs than generalized adiposity assessed using BMI. Several studies have suggested that Asian individuals tend to have increased level of WC (Prasad et al. 2010) with excess body-fat accumulation, abdominal and truncal/regional adiposity and insulin resistance (Hung et al. 2017). Several recent studies have observed strong relationship between waist to height ratio and T2DM (Liu et al. 2016; Hardy et al. 2017; Nagar and Jain 2017; Uday et al. 2017). The conicity index (CI) [$CI = WC(m) / 0.109 \times \sqrt{\{Weight(kg)/ Height(m)\}}$] which was developed as an indicator of obesity can also be used as an anthropometric indicator for T2DM. Body fat distribution and neck circumference (NC) have significant relationship with the occurrence of T2DM and obesity (Marques et al. 2015; Hingorjo et al. 2016; Papazafiropoulou et al. 2016; Wu et al. 2016; Marcadenti et al. 2017). Neck circumference (NC) was also observed to be associated with body adiposity and T2DM (Ghosh and Bandyopadhyay 2014; Marques et al. 2015; Papazafiropoulou et al. 2016; Wu et al. 2016; Marcadenti et al. 2017).

ASSOCIATION OF ADIPOSITY, TYPE-2 DIABETES MELLITUS AND ANTHROPOMETRIC MEASURES

According to WHO (1995, 2000), the health risks increase above the BMI cut-off ≥ 25.00 kg/m² that defined overweight in the current WHO classification (WHO 1995, 2000). According to WHO (2000), greater proportion of Asian people with lower BMI levels than the existing WHO cut-off (≥ 25.00 kg/m²) are at a high risk of T2DM. Due to this variation WHO (2000) has proposed a re-defined criteria of overweight (≥ 23.00 kg/m²) and obesity (≥ 25.00 kg/m²) among Asian populations as instances of co-morbidities and health risk factors occurred at the lower BMI (Table 2). It is evident that the age-sex specific body-adiposity distribution pattern and increase in excess adiposity ethnically vary among populations (WHO 2000; WHO Expert Consultation 2004; Subramanian et al. 2007; Sen et al. 2013). The proportion of Asian populations with a high risk of T2DM are substantial at BMIs lower than the existing WHO cut-off for overweight (BMI ≥ 25.00 kg/m²) and obesity (BMI ≥ 30.00 kg/m²). The cut-offs for observed risk varied from 22.00 kg/m² to 25.00 kg/m² in different Asian populations and the high risk group this cut-off varied from 26.00 kg/m² to 31.00 kg/m². Although, the WHO Expert Consultation (2004) reported that the current BMI cut-off should be retained as the international classification. It has been recommended for the

purpose of public health action. These cut-offs (23.00 kg/m^2 , 27.50 kg/m^2 , 32.50 kg/m^2 and 37.50 kg/m^2) and proposed methods could be considered and countries could make decisions for redefining obesity to take public health action (WHO Expert Consultation 2004). There are evidences of the association between high adiposity levels and the prevalence of T2DM in population (Yajnik 2004; Mohan and Deepa 2007; Mohan et al. 2007; Mondal and Sen 2014; Shrestha 2015; Jain et al. 2017)(Figure 3). The CI is another anthropometric index which is able to identify fat distribution and the risk of diseases therefore used as an indicator of obesity in populations (Roriz et al. 2016). The association between degree of excess adiposity, body-fat distribution and excess weight gain with subsequent incidence of T2DM, CHD and CVD has been examined in several prospective studies (Mohan et al. 2007; Mondal and Sen 2014; Shrestha 2015; Jain et al. 2017). The excess adiposity (e.g., BMI) is now a well-established independent risk factor for their development (Snehalatha et al. 2003; Yajnik 2004; Mohan and Deepa 2007; Mohan et al. 2007; Mondal and Sen 2014; Shrestha 2015; Jain et al. 2017).

ASSOCIATION OF ADIPOSITY, TYPE-II DIABETES MELLITUS AND ANTHROPOMETRY IN ASIAN INDIANS

The prevalence of obesity is considered to be the defined cluster of risk factors for non-communicable diseases (T2DM, CVD, dyslipidaemia and certain types of cancer). Most of the studies assessing the adiposity level have used BMI as an indicator. Several studies showed the need for a national level study based on obesity indices to determine the thresholds for obesity parameters for detecting high risk groups for metabolic abnormalities (Snehalatha et al. 2003; Nandimath et al. 2016). A study to identify obesity thresholds in rural Wardha, India (Deshmukh et al. 2006) showed the threshold for the obesity parameter (e.g., BMI) was same as compared to other studies in Asian Indians. Several recent studies have observed high prevalence of T2DM in Indian populations (Mahalakshmi et al. 2014; O'Keefe et al. 2016). There are geographical variations in obesity parameters and its associations with metabolic abnormalities (Ramachandran et al. 2001). Such regional variations have also been reported in the prevalence of T2DM with increasing BMI (Ramachandran et al. 2001; WHO Expert Consultation 2004). The risk of developing T2DM is high at relatively low BMI values in subjects originating from the South-east Asian populations when compared to the Caucasoids (Snehalatha et al. 2003; Yajnik 2004; Misra and Khurana 2011; Mondal and Sen 2014; Krugger et al. 2017). The BMI might not correspond to the same body-adiposity in different populations because of variations in body proportions, which can be the reason for lower BMI in Indians (WHO 2000; WHO Expert Consultation 2004). The relationship of T2DM and impaired glucose tolerance for BMI value of $>22.00 \text{ kg/m}^2$ had been established in Asian Indian populations (Ramachandran et al. 2001; Snehalatha et al. 2003; Yajnik 2004; Mondal and Sen 2014; Jayawardana et al. 2017). It has also been reported that the South Asian populations have BMI cut-off values lower than the Western populations due to greater level of mortality and morbidities in lower adiposity (WHO 2000; WHO Expert Consultation 2004; Hsu et al. 2015; Kruger et al. 2017). China being the largest developing country in the world is experiencing an epidemic of MetD (Lao et al. 2011; Li et al. 2016) and studies have observed high prevalence of MetD in both North and South China. This prevalence also

varies due to diverse populations of different regions, cultural behaviours, lifestyle habits and the use of different diagnosis criteria (Zhao et al. 2011; Lao et al. 2014; Xiao et al. 2015).

RECENT DEVELOPMENTS IN ANTHROPOMETRY, REGIONAL ADIPOSITY AND TYPE-2 DIABETES MELLITUS

Several recent studies showed that there are many medical conditions e.g., obesity, hypertension, elevated cholesterol levels (combined hyperlipidemia) and other MetDs which are also related to regional adiposity levels and can potentially give rise to T2DM (Alberti et al. 2005; Olokoba et al. 2012). A majority of individuals suffering from T2DM are obese, with central visceral adiposity. Therefore, the deposition of excess adipose tissue plays a crucial role in the pathogenesis of T2DM (Olokoba et al. 2012). Increasing trend of obesity, abdominal obesity and MetD is particularly worrisome since Asian Indians develop T2DM and atherogenic dyslipidemia at lower levels of BMI and WC (Gupta et al. 2012; Bodicoat et al. 2014). Onset of dyslipidemia and MetD are early contributing factors to the onset of T2DM (Gulati and Misra 2017). Several studies have used anthropometry as indicator of T2DM in Indian population using different cut-offs for adiposity levels (Table 3). Studies have shown that the proportion of intra-abdominal visceral adipose tissue specifically truncal/abdominal subcutaneous adiposity is higher in South Asians mainly in those with T2DM (Raji et al. 2001; Anoop et al. 2016; Gulati and Misra 2017). Moreover, a number of recent studies have reported in South Asians that there is excess of deep subcutaneous and abdominal adipose tissue which has high metabolic activity and may cause insulin resistance and CVD (Anand et al. 2011; Marinou et al. 2014). In a recent study by Anoop et al. (2016) it has been found out that increased adipose deposition in liver and pancreas in Asian Indians have potentials of predicting diabetes. Interestingly, the abdominal/regional subcutaneous adipocyte area is increased among South Asians (Anand et al. 2011). Further, Chandalia et al. (2007) observed that subcutaneous adipocyte size was inversely correlated to glucose disposal rate (the rate of glucose uptake from the blood by the peripheral tissues, such as skeletal muscle) in South Asians. This is also independent of intra-peritoneal body adiposity.

Several researchers have reported that heightened insulin resistance in South Asians was observed to be more related to increased truncal subcutaneous fat and adipose tissue dysfunction than to excess intra-abdominal visceral adipose deposition (Chandalia et al. 2007; Anand et al. 2011; Gulati and Misra 2017). Studies have observed low physical activity and low-protein diets among South Asians than among white Caucasians (Bhatt et al. 2012). Another study by Eastwood et al. (2014) observed there are relationships between T2DM, CHD and thigh muscle area which is lower in South Asians. Anbalagan et al. (2013) observed that in South Indian population 39.5% of the patients had pre-sarcopenia (characterized by low muscle mass, without any decrease in muscle strength or physical performance) which was independently associated with diabetes. These associations between adipose tissues/regional adiposity levels and diabetes observed by recent studies suggests that anthropometry by which adiposity levels can be measured almost accurately with high precession can be used as a very important tool in future for detection and screening of T2DM in populations.

Table 3. Indian studies done on type-2 diabetes mellitus (T2DM) or metabolic disorders (MetD) and anthropometry in adults

Population	Region/area	N	Measurements	Cut-off used for BMI or Type-2 Diabetes	Result	Cut-off proposed	Reference
Diabetic and non-diabetic individuals	Central India	100	BMI and Blood pressure	American Heart Association and US Center for Disease Control and Prevention	Anthropometric parameters were found to be high in diabetic subjects compared with non-diabetic subjects.	-	Meshram et al. 2013
Type-2 diabetics and non-diabetics of >30 years of age.	Karnataka, India	700	NC and BMI	WHO (1997) and Yang et al. (2010)	The NC in diabetics was significantly higher than in non-diabetics	-	Aswathappa et al. 2013
Asian Indian youth with type-2 diabetes mellitus and prediabetes	Chennai, India	114	BMI and WC	WHO Consultation group for Diabetes Mellitus (1999)	T2DM in Asian Indian youth and prediabetes subjects had higher BMI, WC and fasting insulin than NCT subjects	-	Mohan et al. 2013
Indian adults (aged: 20-90 years)	States and UT's of India	16,607	Weight, height, WC and BMI	WHO (2006)	29.5% had hypertriglyceridemia	-	Joshi et al. 2014
Overweight and obese people of semi-urban area of Assam	Assam, India	300	Weight, BMI and WC	WHO (2000, 2004)	Prevalence of T2DM and hypertension increases with increasing weight of the individuals	-	Mandal 2014
Healthy adults (20-30 years of age) of Amritsar	Punjab, India	200	BMI, WHR and WHR	WHO (1995, 2000)	All the derived anthropometric indices were significantly increased in young healthy adults (20-30yrs of age) having positive family history of T2DM.	-	Khanna and Sharma 2015
102 individuals	South India	102	BMI, WHR and WC	WHO (2004, 2008)	A strong association between obesity indices and diabetes was identified. BMI and WC could be used in clinical practice for suggesting life style modifications.	-	Awasthi et al. 2017
Indian population	India	875,711	BMI	-	7% adults with diabetes	-	Akhtar and Dhillon 2017
Urban slum	India		BMI, WC and WHR	-	Indian Diabetes Risk Score (IDRS) can be used as an effective tool for screening undiagnosed diabetes	-	Dudeja et al. 2017
Adult patients of type-2 diabetes	Surat, India	120	BMI, WC and WHR	WHO (1995), IDF (2006)	More than half (52.5%) of lean patients and 82.5% of IBW (Ideal Body Weight) patients had abnormal high WHR where as in obese group all patients (100%) were having abnormal WHR.	-	Ganit et al. 2017
Students aged 17-19 years	India	526	BMI	ADA (2005)	BMI and WC estimation can be done for early detection of pre-diabetes in adolescents	Cut-offs for WC for predicting pre-diabetes was found to be ≥ 82.5 cm for boys and ≥ 80.3 cm for girls.	Pandeya et al. 2017

GENETIC AND ENVIRONMENT FACTORS EFFECTING TYPE-2 DIABETES MELLITUS IN ASIAN INDIANS

T2DM being a complex disease involves a wide-range of genetic, lifestyle and environmental factors. Several studies have observed significant associations of T2DM, genetics and environment (Staiger et al. 2009; Banoo et al. 2015; Kharroubi and Darwish 2015) (Figure 3). It is typically a multi-factorial disease involving multiple genes and various environmental factors with different extents. Moreover, it is not an autoimmune disorder (Banoo et al. 2015). In most of the individual or populations there are susceptible genes predisposing to NIDDM which have not been identified till now (Banoo et al. 2015). Heterogeneity of the genes responsible for the susceptibility to T2DM may be one of the reasons for this problem of identification (Banoo et al. 2015). The variations in T2DM are directly or indirectly affected by overall genetic background of the individual, family or populations which are further more complicated by the interaction with variable environmental conditions/factors (Staiger et al. 2009; Kharroubi and Darwish 2015). Although, there are problems of identification of the genes but several research studies have observed genetic susceptibility of T2DM. Studies have also reported more than 200 T2DM susceptible genes such as Insulin receptor, GLUT, Glycogen Synthase (Mahajan et al. 2014; Zhao et al. 2017). Association between genetic polymorphisms and T2DM have also been observed in the genes encoding the peroxisome proliferators activated receptor, Insulin Receptor Substrate, inward rectifying potassium channel, zinc transporter and calpain-10 (Ali 2013; Banoo et al. 2015). The mechanisms increasing susceptibility of these genetic loci to T2DM are not clear, but most of them are predicted to be altering the function/ development/ insulin secretion (Banoo et al. 2015). Studies have observed Caucasians are affected by T2DM by 1 to 2% but it is much higher in some ethnic groups e.g., Pima- Indians and Arabs among South Indians it approaches 50% (Banoo et al. 2015). The risk of diabetes increases with age and in most of the cases it has been diagnosed at the age of 40 years and above. It is becoming an epidemic in some countries due to increase in aging population.

Genetic predisposition is a major reason among Asian Indians also called as “*Asian Indian phenotype*” which contributes to the increased predisposition of T2DM among Asian Indians (Mohan et al. 2007; Vimalaswaran et al. 2016; Soares and Müller 2017). Despite having lower prevalence of obesity as defined by BMI, Asian Indians tend to have greater WC and WHR thus having a greater degree of central obesity. Other reasons of T2DM are fast food culture and sedentary lifestyle in Indian population due to the major epidemiological changes going on in the country (Deepa et al. 2017; Mastorci et al. 2017). Genetic factors play an important role in the development of T2DM and mutations in a single gene or a multi-factorial origin can act as the genetic cause of T2DM (Horikawa et al. 2000; Kharroubi and Darwish 2015).

EFFECT OF MIGRATION AND TYPE-2 DIABETES MELLITUS IN ASIAN INDIANS

Several studies worldwide on migrant Indians have shown that Asian Indians have an increased risk of developing T2DM and related metabolic abnormalities (e.g., MetDs) compared to other ethnic groups (Mohan et al. 2007; Soares and Müller 2017). Genetic factors and environmental conditions are the main causes of these physiological conditions among Asian Indians. Migration is the movement of individual/population from one environment to another and it can bring several changes due to external or internal factors (e.g., social and cultural changes) among population. Studies have reported that migration from rural areas to urban slums in a metropolitan city in India have led to obesity, glucose intolerance and dyslipidaemia (Mohan et al. 2007). Several factors include genetic and pre-migration history (e.g., socioeconomic level, lifestyle habits, exposure to infections), as well as the quality of healthcare in the countries of destination controls the link between migration and prevalence of disease (Montesi et al. 2016; Girardi et al. 2017). Moreover, there are many factors (viz., urbanization, mechanization, changes in nutrition and lifestyle including physical inactivity, genetic environment/susceptibility interactions and stress) which expose the migrants to a higher risk of developing certain diseases after arrival in the host countries (Misra and Ganda 2007; Montesi et al. 2016; Girardi et al. 2017). Several conditions experienced by migrants moving from a poverty-ridden rural area in early life to an obesogenic urban environment in their later life increases the risk of obesity and T2DM among both inter- and intra-country migrants in developed and developing countries (Girardia et al. 2017). The adoption of sedentary lifestyles and availability and abundance of calorie-dense/low fibre foods is associated with increased risks of morbidity and mortality among the migrated populations. Several studies have investigated the link between migration and T2DM (Misra and Ganda 2007). Several studies have also reported that migration itself contribute to the increase in truncal/subcutaneous abdominal adiposity, which is also an observed phenomena in Asian Indians and South Asians (Raji et al. 2001; Girardiet al. 2017).

ASIAN ENIGMA IN REGIONAL ADIPOSITY, METABOLIC DISORDERS AND TYPE-2 DIABETES MELLITUS

Several studies have observed that South Asian populations have 3%-5% of greater body-adiposity than Caucasians at any given BMI with low adipokine production, lower lean body mass. Ethnic/genetic, environment, demographic, cultural, lifestyle and socioeconomic factors are being considered as potential contributors to an early age-onset of obesity-linked CVD risk and MetDs (WHO Expert Consultation 2004; Prasad et al. 2010; Misra and Khurana 2011; Hudda et al. 2017). The WHO has revised the BMI cut-off for Asian Indians and suggested a BMI ≥ 25.00 kg/m² to define obesity against the ≥ 30.00 kg/m² recommended for Europeans (WHO 2000) (Table 1). Asian Indians have the increased predispositions to T2DM (WHO 2000; WHO Expert Consultation 2004; Yajnik 2004; Ramachandran et al. 2014). This predisposition has been attributed to the Asian Indian Phenotype which is characterized by lesser than the generalized obesity as measured by BMI but greater than the

central obesity with respect to the WC and WHR (WHO 2000; Prasad et al. 2010; Vimalaswaran et al. 2016; Little 2017). This is the cause of biochemical and hormonal changes including higher plasma insulin levels, greater insulin resistance, lower HDL cholesterol, higher triglyceride levels, increased small dense LDL cholesterol as well as small dense HDL cholesterol and C-reactive protein and leptin levels but decreased adiponectin levels (Lele et al. 2006; Manoria et al. 2010). Asian Indians have higher total abdominal and visceral adiposity for any given BMI (WHO Expert Consultation 2004; Raji et al. 2001) and for any given body adiposity they have increased insulin resistance (Soares and Müller 2017). Other studies have shown that some genes seem to confer increased susceptibility to diabetes in Indians (Vimalaswaran et al. 2005). Europeans have some type of protective genes which do not appear to protect Indians (Radha et al. 2006; Radha and Mohan 2007). It is evident that the abdominal or central/regional obesity is closely linked with insulin resistance, enhanced lipolysis and release of free fatty acids which inhibits insulin stimulated peripheral glucose uptake in dose dependent manner while simultaneously inhibiting insulin secretion (Mohan and Rao 2007; Prasad et al. 2010). These features have been referred to as the Asian Indian Phenotype or Paradox (Vimalaswaran et al. 2016; Little 2017). Several studies on neonates have suggested that Indian babies are smaller born but relatively fatter compared to Caucasian babies and are referred to as “the thin fat Indian baby” (Yajnik et al. 2003; Krishnaveni et al. 2005). Neck circumference (NC) is also observed to be associated with the occurrence of MetDs (Hingorjo et al. 2016). Anthropometric measures which have strong association with the occurrence of T2DM can contribute highly in risk detection of T2DM in populations worldwide. Anthropometric measures (e.g., BMI, WHR, WC, NC and CI) can also be used very accurately to control and/or monitor the increasing trend of T2DM/MetDs in population.

LIMITATION OF ANTHROPOMETRIC MEASURES

Several research studies have reported the associations between anthropometry and MetD, but several questions critical to the use of anthropometry as a direct indicator of MetD or T2DM remain in doubt. It is important to test whether standard metrics of adiposity used in clinical settings (e.g., BMI, WC, WHR and CI) adequately reflect the accurate level of visceral (or subcutaneous) adiposity and the subsequent risks of MetD as well as T2DM. Whether only the high adiposity levels alone explains the cause of MetD or T2DM remains unanswered due to the effect of environmental factors, genetic predisposition to the disease as well as other external factors (viz., socioeconomic, occupation, migration, lifestyle effect, predisposition to other diseases and early life experiences). In this context anthropometry has its limitation because biochemical and genetic methods can give much greater accurate measure of MetD as well as T2DM.

CONCLUSION

The prevalence of T2DM is reaching potentially epidemic proportions in India. The mortality and morbidity associated with T2DM and the potential complications associated with T2DM are enormous, and pose significant burdens of healthcare on both families and

society. Therefore, it is very necessary to detect and control the risks of T2DM by using improved intervention techniques and policies. There are evidences from recent studies that strong associations between anthropometric, genetic and biochemical risk for T2DM as a non-communicable disease and MetD are present in populations. Due to the wide population diversity of India based on ethnicity, culture, socioeconomic conditions, resource distribution and nutritional conditions the need for establishing ethnic-specific anthropometric (e.g., BMI, WC and WHR) cut-offs are becoming very much necessary for the proper identification of the relative risks of MetDs and T2DM. Moreover, practical implementations of those cut-off values of anthropometric measures are very necessary. It is possible to minimise the relative risks by only controlling the lifestyles of the individuals and therefore it is very necessary to introduce region/ethnic specific policies to control T2DM and MetDs. Prevention of T2DM and its micro- and macro-vascular complications should be an essential component for future public health strategies for the countries. Collection and reporting of obesity data should be systematically included in all nutrition surveys which are very necessary in prevention of T2DM and MetDs. Extensive studies by researchers are necessary for establishing proper measure for assessing the risk of T2DM in terms of adiposity levels/regional body adiposity as several recent studies have observed significant association between regional adiposity and T2DM and/or MetDs in populations. Moreover, epidemiological and operational information on obesity and T2DM should be integrated into existing international nutrition forums. Proper lifestyle modifications should be induced in populations to minimise the prevalence of T2DM. Also, public/private partnerships are necessary to properly implement the public healthcare policies for controlling the epidemic of T2DM/MetDs. A large proportion of cases of T2DM are preventable therefore initiatives for consumer education to promote a healthy diet could be reinforced by government's involvement towards the problem.

INTRODUCTION

Type II Diabetes: A Global Menace

Type II diabetes mellitus is a long term metabolic disorder that consists of an array of dysfunctions characterized by hyperglycemia and resulting from the combination of resistance to insulin action, inadequate insulin secretion, and excessive or inappropriate glucagon secretion. Common symptoms include increased thirst, frequent urination, and unexplained weight loss. Symptoms may also include increased hunger, feeling tired, and sores that do not heal (NIDDKD, 2014). Long-term complications from high blood sugar include heart disease, strokes, diabetic retinopathy which can result in blindness, kidney failure, and poor blood flow in the limbs which may lead to amputations (WHO 2011).

Globally, an estimated 422 million adults are living with diabetes mellitus, according to the latest 2016 data from the World Health Organization (WHO 2016). Diabetes prevalence is increasing rapidly; previous 2013 estimates from the International Diabetes Federation put the number at 381 million people having diabetes. The number is projected to almost double by 2030. Type II diabetes makes up about 85-90% of all cases (New York Times 2006). Increases in the overall diabetes prevalence rates largely reflect an increase in risk factors for Type II, notably greater longevity and being overweight or obese (Melmed et al., 2011).

* Corresponding Author's Email: rgoswami77@gmail.com.

Indian Scenario

Until recently, India had more diabetics than any other country in the world, according to the International Diabetes Foundation, although the country has now been surpassed in the top spot by China, Diabetes currently affects more than 62 million Indians, which is more than 7.1% of the adult population. The average age on onset is 42.5 years. Nearly 1 million Indians die due to diabetes every year (Gale 2010).

According to the Indian Heart Association, India is projected to be home to 109 million individuals with diabetes by 2035 (IHA 2016). A study by the American Diabetes Association reports that India will see the greatest increase in people diagnosed with diabetes by 2030. The high incidence is attributed to a combination of genetic susceptibility plus adoption of a high-calorie, low-activity lifestyle by India's growing middle class (New York Times 2006).

A considerable variability in the incidence and prevalence of Type II diabetes (T2D) coheres with an important contribution of multigenetic predisposition in the development of T2D. Some genes, which probably participate in the pathogenesis of Type II diabetes, also play a role in the regulation of blood pressure, familial hyperlipidemia, familial hypertension and other diseases of the cardiovascular system Demova et al., 2012.

Human C-reactive protein (CRP) is an acute phase reactant involved in chronic and acute inflammation. CRP production is rapidly stimulated in response to infection, tissue injury or inflammation. In a recent study, increased levels of CRP are reported to be associated with metabolic syndrome, obesity, atherosclerosis, unstable angina, insulin resistance and diabetes. Family and twin studies suggest that genetic factors account for 40% of the variance in plasma CRP levels + 1059 G > C (rs1800947) is a single nucleotide polymorphism (SNP) in exon 2 of the *CRP* gene. + 1059 G > C is a silent or synonymous polymorphism at the amino acid level (CTG → CTC, Leu → Leu at codon 184) which has been reported to affect the protein levels of CRP and contribute towards the progression of CAD (coronary artery disease) and T2D Kaur et al., 2013.

METHODS

Study Population

This is a longitudinal follow-up study and present study was being done in continuation with the earlier work. The medical history of the patient's family was recorded. Determination of presence or absence of other risk factors – high cholesterol levels, cigarette smoking, hypertension, and diabetes in first-degree relatives (biological parents, siblings, and offspring) – was recorded. The present study was conducted on 160 healthy (non-diabetic, normotensive) adult Asian Indian women [including 90 with and 70 without family history of diabetes (FHD)] living in and around Kolkata, India. This sample size was sufficient to test all the research hypotheses at the 5% level of significance. During the gestation period they were studied twice, first within 12 weeks and second by 30 weeks. They were then followed up till delivery. During delivery both mothers' venous blood and cord blood were collected to estimate the metabolic variables and genetic polymorphisms of the respective mothers and

their new born babies. All the experiments were done according to the “Ethical guidelines for Biomedical Research on Human Participants” published by Indian Council of Medical Research (2006). The Institutional Ethics Committee (IEC) of Heritage Institute of Technology, Kolkata, approved the study. Written consent was obtained from the subjects prior to actual commencement of the study.

Anthropometric Measurements

Demographic profiles including name and age were obtained from participants. Informed consent was obtained from participants prior to the actual commencement of the study. Height was measured to nearest 0.1 cm with a Martin’s Anthropometer and weight to the nearest 0.5 kg with a portable weighing machine in light clothing and bare feet.

Blood Pressure Measurements

Left arm systolic (SBP) and diastolic (DBP) blood pressure was taken from each participant with the help of an Omron M1 digital electronic blood pressure/pulse monitor (Omron Corporation, Tokyo, Japan). Two blood pressure measurements were taken and averaged for analysis. A third measurement was taken when the difference between the two measurements was ≥ 5 mmHg, and a subsequent mean was calculated. A five minute relaxation period between measurements was maintained for all participants. The working condition of the instrument was checked periodically using a mercury sphygmomanometer and stethoscope (auscultator procedure). Subjects with SBP/DBP values $> 130/85$ mm Hg were considered as Hypertensive, according to NCEP and ATPIII guidelines, 2005 (NCEP 2005).

Estimation of Metabolic Profiles

A fasting blood sample (7 ml) was collected from each subject for the determination of fasting blood glucose (FBG), Total cholesterol (TC), Triglycerides (TG), and High density lipoproteins (HDL). All subjects maintained an overnight fast of ≥ 12 h prior to blood collection. The plasma was separated within 2 h of blood collection using a microcentrifuge at 1000 rpm for about 20 min at room temperature. Estimation of FBG, TC, TG, CRP and HDL were carried out using a Robonik Biochemistry Analyzer (Robonik India, Mumbai, India). Low-density lipoprotein (LDL) and very low density lipoprotein (VLDL) were then calculated by using the standard formula: $LDL = TC - (HDL + TG/5)$ and $VLDL = TG/5$. All the metabolic profiles were estimated according to NCEP and ATPIII guidelines 2005 (NCEP 2005).

Genotyping of CRP

- The DNA was isolated from whole blood by HiPurA™ Blood Genomic DNA Miniprep Purification Spin Kit. The DNA was amplified by PCR (ABI Biosystems, USA).
- Amplification refractory mutation system-polymerase chain reaction (ARMS-PCR) which is based on allele specific amplification of desired fragment using primers corresponding to the alleles has been used for genotyping of +1059 G > C SNP in the CRP gene.
- The sequences of specific primers used are:
 1. Constant forward:
5'-CATTGTACAAGCTGGGAGT-3',
 2. Allele C-specific reverse:
5'-ATGGTGTTAATCTCATCTGGTGGG-3',
 3. Allele G-specific reverse:
5'-ATGGTGTTAATCTCATCTGGTGGC-3'.
- The conditions included initial denaturation (95°C for 5 min) following a touchdown PCR with denaturation at 94°C for 45 secs, annealing at 66°C to 62°C with 1°C decrease in temperature for the first 4 cycles followed by 29 cycles at 61°C for 45 secs, extension at 72°C for 45 secs each cycle and final extension at 72°C for 10 min (Cao & Hegele 2000).
- CRP+1059 G > C genotypes were assessed from the presence/absence of PCR amplicon (237 bp), corresponding to the specific allele (C/G) on 1.5% agarose gel stained with Ethidium bromide.
- The genotyping of CRP genes yielded PCR products of size 744 bp. Digestion of the less common 1059C allele produced two smaller fragments, with sizes of 434 and 310 bp. Digestion of the more common 1059G allele produced three fragments, with sizes of 310, 233, and 201 bp.

Statistical Analyses

Mean and SD for all the metabolic variables, hormones and blood pressure measurements were calculated by conventional statistical methods. Group differences (with and without FHD) for all the variables (18 and 30 months) were tested by One-way ANOVA ($p \pm 0.05$). Differences in CRP values by FHD were estimated by 2X2 Contingency Chi-square analysis ($p \pm 0.05$). Differences in birth outcomes by FHD and CRP values of mothers was estimated by Chi-square analysis ($p \pm 0.05$). All statistical tests were performed on Statistical Package for Social Sciences (IBM-SPSS version 16) and significance was set at $p < 0.05$ two tailed.

RESULTS

Biochemical Analyses of Metabolic Risk Factors

Statistical Analyses of the comparison of the Group differences (with and without FHD) for all the variables (12 and 30 weeks) were tested by One-way ANOVA ($p < 0.05$). Table 1 shows the anthropometric measurements and biochemical parameters which were considered during the study.

A comparison of the metabolic variables among the subjects with and without FHD revealed that there were significant differences among them with respect to Waist circumference, Triglycerides, HDL-Cholesterol, VLDL-Cholesterol, Fasting Blood Glucose and Blood pressure, both at the gestational period of 12 weeks and 30 weeks. It indicates that family history plays an influencing metabolic factors and triggering the risk factors early in the gestational phase leading to complications in adult life.

Table 1. Baseline characteristics of the study population by family history (n = 160)

VARIABLES	BY 12 WEEKS			BY 30 WEEKS		
	Both/Either*	None**	ANOVA	Both/Either	None	ANOVA
	(n = 90)	(n = 70)	P	(n = 90)	(n = 70)	P
AGE (yrs)	31 (6.3)	27 (3.2)	0.258	32 (6)	30 (6)	0.323
WEIGHT (kg)	68 (13)	63 (8)	0.240	74 (10)	72 (10)	0.061
BMI (kg/m ²)	25.4 (3.8)	27.3 (3.7)	0.415	36.5 (4.1)	32.5 (3.9)	0.416
WC (cm)	91 (13)	79 (9)	<0.001	132 (14)	110 (12)	<0.001

TG (mg/dl)	159 (27)	124 (21)	<0.001	243 (32)	176 (29)	<0.001
HDLc (mg/dl)	54 (9)	44 (10)	<0.001	53 (8)	42 (9)	<0.001
LDLc (mg/dl)	115 (11)	100 (12)	0.001	117 (13)	108 (10)	0.009
VLDLc (mg/dl)	35 (5)	28 (4)	<0.001	55 (10)	34(7)	<0.001
FBG (mg/dl)	117 (10)	98 (12)	<0.001	110 (12)	94 (11)	<0.001
SBP (mmHg)	122 (11)	108 (12)	<0.001	138 (14)	118(16)	<0.001
DBP (mmHg)	83 (10)	77 (9)	<0.001	95 (8)	88 (6)	<0.001

Read as Mean and $\pm$ SD within parentheses; *Both/Either - Participants having positive FHD present in both or either parents; **None - No FHD.

Figure 1. Showing statistically significant difference in C-reactive protein (CRP) levels by FHD ($p = 0.0109$).

Figure 2. Showing statistically significant differences in birth outcomes (birth weight in kg) by FHD and CRP of the mothers ($p = 0.0252$).

Table 2. Differences in C-reactive protein (CRP) of the babies by mothers' CRP and FHD

CRP of the Babies	Mothers with +FHD and high CRP (n = 66)	Mothers with -FHD and normal CRP (n = 45)	ANOVA
Mean	0.45	0.25	P < 0.001
SD	± 0.087	± 0.025	

Figure 3. Showing genotyping results of CRP genes of newborn babies, w.r.t their mother's health status.

Comparison of subjects in the CRP levels between the same groups also revealed a statistically significant difference in subjects with a positive FHD and high CRP levels in comparison to normal cases (Figure 1 & 2).

Comparison of birth outcomes in terms of birth weights was done between subjects with and without a positive family history of T2DM and high CRP levels (Figure 1), which revealed a significant difference between the two groups. This shows that family history and perturbations in the gestational period are reflected in the birth outcomes, affecting the next

generation (Table 2). It is evident from the results that there is a significant difference in inflammatory status in those newborns whose mothers have a positive FHD compared to their normal counterparts.

DISCUSSION

The Family History of Diabetes (FHD), evidently, has been found to be most useful for predicting T2DM when the disease is premature, that is, it occurs at younger ages than would be expected. This FHD information in combination with other known risk factors could be used to provide more personalized information about our risk for such diseases. Yang et al., (2010) further suggested that adding FHD could provide significant improvements in detecting undiagnosed diabetes; however, it needs further validation with larger cross-sections of population. In another study, it was found that not only the adults but even the young population with a positive FHD showed signs of increased risk for these conditions which indicates the importance of family history approach to screening for children at risk of T2DM and CVD (Valdez et al., 2007).

In our present study, we noticed a population trend where individuals with positive family history of diabetes had significantly higher prevalence of metabolic risk factors and its confounding factors as compared to their counterparts during pregnancy, which is also affecting their next generation leading to childhood obesity. Therefore, based on this observation, it can be stated that positive FHD and CRP status plays an important role in triggering the activation of metabolic risk factors during the pregnancy period, and this could be one of the major factors for development of T2DM and metabolic syndrome in the next generations. These findings suggest that family history could be used as a tool for genomic studies among the Asian Indians.

CRP is a potential biomarker for prediction of future risk of cardiovascular disease (CVD) both in diabetic and non-diabetic individuals, because even a small rise in plasma CRP levels leads to cardiovascular events. In the present investigation of the association of CRP+1059 G>C polymorphism with the progression to T2D, we have observed that the frequency of G-allele is high in the Asian Indian population (70%). Similarly high frequency for the G-allele (~90.0%–96.3%) has been reported in studies conducted on other world populations (Pasalic et al., 2009; Tanja et al., 2008).

Heterozygous carriers of C allele (GC) in the present studied population have shown protection towards the disease manifestation. The GC genotype is highest in controls (9.8%) as compared to cases (2.3%–3.4%) suggesting that some kind of selection pressure is operating on the GC genotype. Considering the thrifty genotype hypothesis, the ancestral version of the alleles proves to be deleterious in the present day environment while the rarer alleles which may have protective effects against the disease have evolved lately (Sharma 1998). Fernandez-Real and Ricart have implicated the role of genes encoding for cytokine synthesis as thrifty genes (Fernandez-Real & Ricart, 1999). The hypothesis suggested that higher secretion of cytokines and increased acute phase response were an evolutionary adaptation to phases of acute infections and trauma. In the ancestral period, outbreaks due to infections were higher. Simultaneously due to exposure to famines, metabolic pathways favored insulin resistance to survive in low food situations. It has been proposed that insulin

resistance and cytokine responder genotypes were favorable adaptations to low fat, high fiber and high physical activity environment. The genomes of the present day human are still genetically adapted to ancestral conditions which are designed to fight against infection with minimal food intakes and high physical activity. However, environmental transition is more rapid, and evolution being a slow process, our genotypes have not modified according to the present day environments of lower infections, availability of surplus food and low physical activity. In the absence of the favorable conditions and with advancement of age, insulin resistance ensues which further activates inflammatory cascade that eventually results in atherosclerosis. Thus, in the presence of insulin resistance genotypes and western lifestyle, a high cytokine responder genotype would be more prone to develop T2D and atherosclerosis. Although +1059 G > C polymorphism is a silent polymorphism, yet the ancestral allele of the polymorphism (G-allele) has been associated with higher CRP levels in various studies as discussed above. Higher CRP levels are suggestive of inflammatory response which may get accentuated in the background of obesity and insulin resistance condition in T2D. The higher frequency of the G-allele in most of the populations and the protective effect of GC genotype in the present study could be viewed in the background of its role as a thrifty genotype.

CONCLUSION

From our study, we therefore can conclude that the CRP +1059 G > C polymorphism seem to have functional effects on protein production (Eklund et al., 2005). It has also been proposed that silent SNPs can lead to protein product with the same amino acid sequence, but with different structural and functional properties which might play an important role in defining the protein levels (Radha & Mohan 2007). The reason for discrepancies in association studies across populations may be explained by diverse ethnic background of different populations as different ethnic groups have different susceptibility towards the disease (Komar 2007).

Taken together, these observations raise the possibility that these polymorphisms in combination with both family history and environmental factors may account for the phenotype of peripheral insulin resistance and impaired insulin secretion, the two typical features of Type II diabetes.

Also, having observed that family history of diabetes (FHD) is indeed an important and independent risk factor for genomic studies of complex diseases like T2DM, efforts should be made toward translating this knowledge for use in public health programmes designed to detect and prevent diabetes. Once this is achieved, FHD should be incorporated into the screening and prevention programmes for T2DM as rigorously as possible to make these programmes significant and cost-effective.

However, the present study has several limitations. In the limitations of the present study, firstly, the association of polymorphism with the protein levels needs to be established. Secondly further studies relating the protein levels with studied polymorphism and other functionally relevant polymorphisms which may be in LD with the studied SNP are required on larger sample size to validate the findings of the present study with more statistical power.

Chapter 251

SENSITIVITY AND SPECIFICITY OF BODY MASS INDEX TO ASSESS EXCESS ADIPOSITY

Jyoti Ratan Ghosh*

Department of Anthropology, Visva-Bharati, Santiniketan,
West Bengal, India

INTRODUCTION

Since the introduction of the Quetelet index (QI) {body mass index (BMI)} in 1832 (Eknoyan, 2008), it was widely used as a measure of excess adiposity or obesity (Price et al., 2018; Volkovicher et al., 2018). Not only that, BMI was also found to be associated with different metabolic and physiological abnormalities (Ghosh and Bandyopadhyay, 2007; Xu et al., 2008; Kaplan et al., 2014; Leonska-Duniec et al., 2018). However, epidemiological studies in Asian populations, especially in Indians revealed higher prevalence of cardiovascular disease and type 2 diabetes with a lower mean BMI, but interestingly had higher percent body fat (PBF) at a corresponding BMI value than Europeans (Razak et al., 2007; Xu et al., 2008). Therefore, using a BMI cut-off value based on adult Europeans may not truly identify Asian Indians with excess adiposity, as the relationship between BMI and PBF varied among different ethnic groups (Gurrici et al., 1998; Deurenberg et al., 2000).

As a consequence, in 2000 a WHO expert consultation on the obesity issues in Asia–Pacific region suggested redefining the criteria for obesity, recognizing the necessity for ethnic specific cut-off points. However, they recommended that the conventional (WHO, 1995) BMI cut-off point of ≥ 30 kg/m² should be retained as an international classification for obesity. In a publication of this WHO consultation, the proposed BMI cut-off point for overweight was 23–24.9 kg/m², and that for obesity was ≥ 25 kg/m² (WHO, 2000).

In a succeeding publication in 2004, another WHO consultation resolved that the available data do not necessarily indicate one clear BMI cut-off for all Asian Indians for overweight and obesity. No attempt was made therefore to redefine cutoff points for each population separately (WHO, 2004).

* Corresponding Author's Email: jrgghosh@visva-bharati.ac.in.

In the present study, an attempt has been made to test the ability of different BMI cut-off points to predict high percent body fat by sensitivity/ specificity analysis. This would help to develop population specific BMI cut-off value for identifying individuals with truly excess adiposity. This was more important for Asian populations, because for every level of BMI the predicted fat mass was higher in Asian populations (Dudeja et al., 2001; Deurenberg et al., 2002). Thus, the purpose of this study was to examine the sensitivity and specificity of BMI in adult Asian Indian women to detect excess adiposity.

MATERIALS AND METHODS

The present community-based cross-sectional study comprised adult Asian Indian women living in and around Kolkata, India. A total of 364 participants aged 18–70 years took part in the study. Pregnant and lactating women, women undergoing hormone therapy as well as under medication or with chronic disease were not included in the study. Prior to participation, individuals were informed by public advertisement and oral communication about the study with the help of the local officials. Individuals who responded to the advertisement were selected randomly. Informed verbal consent was obtained from each participant before commencement of the study. Age was obtained by interview and verified with horoscope or birth certificate whenever possible.

Anthropometric measurements namely height (HT) and weight (WT) were measured using standard procedures (Lohman et al., 1988). HT was measured to the nearest 0.1 cm using moveable anthropometer. WT was measured to the nearest 0.5 kg using weighing machine. BMI (kg/m^2) was derived subsequently. Percent body fat (PBF) was measured using bioelectrical impedance analysis (BIA) (OMRON HBF-302). Several studies have shown a strong correlation between PBF, FM, and FFM as measured by BIA and dual-energy-X-ray-absorptiometry (DEXA) (Goldfield et al., 2006; Boneva-Asiova and Boyanov, 2008). The BIA has also been validated for Asian Indians (Vasudev et al., 2004).

Descriptive statistics for anthropometric variables were computed by mean and standard deviation (SD). Pearson correlation coefficient was used to quantify the relation between BMI and PBF. The receiver operating characteristic (ROC) curve analysis was used to evaluate the ability of BMI for assessing excess adiposity and the accuracy was determined by examining the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), Youden's index and overall misclassification. Excess adiposity was defined as total body fat greater than thirty percent (Hortobagyi et al., 1994; Dudeja et al., 2001). Statistical analyses were performed using the Statistical Package for Social Sciences (SPSS). A p value of <0.05 was considered as significant.

RESULTS

Characteristics of the studied population are shown in Table 1. The mean age was 31.88 years (SD 14.26 years), with a range of 18 to 70 years. The mean BMI and PBF was 23.61 kg/m^2 (SD 4.43) and 28.47 (SD 6.45), respectively. When conventional BMI cut-off value of $\geq 30 \text{ kg/m}^2$ was applied, 30 (8.2%) women were obese or have excess adiposity. However, the

result varied considerably when PBF was used as the measurement of excess adiposity. Based on PBF, 132 (36.3%) women had excess adiposity. Result of the Pearson correlation analysis revealed significant positive correlation between BMI and PBF ($r = 0.561$) and BMI explained 31.4% of variance of PBF ($p < 0.01$). Table 2 shows the results of the ROC curve analysis for the BMI cut-off values in relation to excess adiposity by PBF. The results revealed that the sensitivity and specificity as well as the PPV and NPV of the conventional BMI cut-off value for excess adiposity were 18.93%, 97.84%, 83.32% and 67.93%, respectively. However, based on the ROC curve (Figure 1) and the trade-offs between improving BMI's sensitivity and specificity, the optimal cut-off value was BMI ≥ 23.4 kg/m² with a sensitivity and specificity 77.27% and 72.84%, respectively in assessing excess adiposity. With this cut-off value, the sensitivity of BMI in relation to PBF increased but the PPV was low. Moreover, lowering the BMI cut-off value from ≥ 30 kg/m² to ≥ 23.4 kg/m² increased Youden's index from 0.17 to 0.50 and decreased overall misclassification 5.22%.

Figure 1. Receiver operating characteristic curve of BMI (kg/m²) in assessing obesity.

Table 1. Characteristics of the study population

Variables	Mean	SD
Age (year)	31.88	14.26
Height (cm)	152.81	6.14
Weight (kg)	55.19	11.13
Percent body fat	28.47	6.45
Body mass index (kg/m ²)	23.61	4.43

SD, standard deviation.

DISCUSSION

The present study examined the sensitivity and specificity of BMI to detect excess adiposity in adult Asian Indian women. In epidemiological studies and in clinical practice BMI was widely used as a proxy measure of excess adiposity. However, the efficiency of BMI is depends on its sensitivity and specificity to detect excess adiposity. This varied with

ethnicity, due to the biological variation in body shape and composition. However, the ROC curve analysis in the present study demonstrated low sensitivity (18.93%) and high specificity (97.84%) of the conventional BMI cut-off value to detect excess adiposity. Such a low value of sensitivity and high specificity suggested that this BMI cut-off value failed to detect excess adiposity in ~ 80% of subjects who had truly excess adiposity. In other words, conventional BMI cut-off value was not useful to detect individuals with excess adiposity. A recent study in Saudi adults also revealed low sensitivity and high specificity of BMI in assessing excess adiposity (Habib, 2013). Study in Asian-American women also revealed poor sensitivity of BMI to detect PBF (Carpenter et al., 2013). Dudeja et al. (2001) and Hortobagyi et al. (1994) also observed similar results.

The ROC analysis revealed that the best compromise between sensitivity and specificity for optimal BMI cut-off value to detect excess adiposity was 23.4 kg/m², and the corresponding sensitivity and specificity was 77.27% and 72.84%, respectively. However, this cut-off value was lower than the conventional cut-off value to detect excess adiposity and thus, could identify individuals who would otherwise be considered as normal by the conventional cut-off value. In relation to the conventional cut-off value for excess adiposity, a lower BMI cut-off of 23.4 kg/m² produced increased sensitivity (18.93% vs. 77.27%) and moderately decreased specificity (97.84% vs. 72.84%). In reality, it was difficult to achieve high sensitivity and specificity simultaneously, thus relative importance of sensitivity vs. specificity was taken into consideration. However, the BMI cut-off value of 23.4 kg/m² instead of 30 kg/m² increased the likelihood (Youden's index 0.50 vs. 0.17) ~ three times for detecting individuals with excess adiposity, who had truly excess adiposity. Additionally, this lower BMI cut-off value decreased 5.22% overall misclassification. However, it is noteworthy to mention that for women in our sample, the proposed BMI cut-off value (≥ 25 kg/m²) of WHO (2000) revealed only 44.7% sensitivity and 83.6% specificity. In a study, Bozkirli et al. (2007) also observed that the conventional BMI cut-off value underestimated the prevalence of excess adiposity in Turkish population. Moreover, several other studies also revealed that lowering the BMI cut-off value improved its ability to assess excess adiposity (Dudeja et al., 2001; Ko et al., 2001; Ghosh and Bandyopadhyay, 2007).

Table 2. Sensitivity and specificity of BMI (kg/m²) as a measure of obesity

Cut-off points	Sensitivity (95%CI)	Specificity (95%CI)	PPV	NPV	Youden's index	Overall misclassification
BMI ≥ 30 kg/m ²	18.93% (14.9-22.9)	97.84% (96.4-99.3)	83.32%	67.93%	0.17	30.78%
BMI ≥ 25 kg/m ²	44.7% (39.6-49.8)	83.6% (79.8-87.4)	60.83%	72.62%	0.28	26.64%
BMI ≥ 23.4 kg/m ²	77.27% (73.8-80.8)	72.84% (68.3-77.4)	61.81%	84.91%	0.50	25.56%

PPP, positive predictive value; NPV, negative predictive value; BMI, body mass index

The cardinal feature of the present study was the predictive values (i.e., PPV and NPV) of BMI in relation to the PBF. As shown by the PPV of the conventional BMI cut-off value, almost 17% of women with high PBF (PBF >30%) had BMI < 30 kg/m². On the other hand, high NPV indicates that almost one out of three (~32%) women with normal PBF (<30%) had

high BMI (≥ 30) kg/m². However, the PPV of the optimal BMI cut-off value in our sample was 61.81%. Indicated that approximately 38% of women who had a BMI ≥ 23.4 kg/m² did not have high PBF ($< 30\%$). Thus, the results indicated that BMI was a relatively poor predictor of excess adiposity in the studied population. One possible reason might be the weaker association between BMI and PBF in the studied population. Because, BMI as a proxy measure of adiposity explained only 31.4% of variance of PBF. A recent study by Carpenter et al. (2013) also observed weak association between BMI and PBF among Asian-American women.

Moreover, the weak association between BMI and PBF might be due to the fact that BMI does not measure fat mass or percentage fat only, but measures both fat mass and fat free mass without distinguish between them (Garn et al., 1986; Hortobagyi et al., 1994; Charbonneau-Roberts et al., 2005; Rona et al., 2011). Therefore, individuals with the same BMI may have different proportions of fat mass. Furthermore, it has been observed that BMI underestimate excess adiposity among those with long legs and overestimate excess adiposity among those with short legs relative to torso length (Garn et al., 1986; Charbonneau-Roberts et al., 2005).

CONCLUSION

Therefore, measuring body fat instead of BMI could be an appropriate way to categorize individuals with excess adiposity. Although BIA is a validated measure of body composition, acknowledging that the use of more accurate measures like DEXA would have improved our analysis. However, this preliminary finding warranted further studies in other Asian ethnic groups to understand whether the same relationships exist. Since, it is the amount of excess body fat, rather than the amount of excess weight that determines the health risks of obesity (Deurenberg et al., 1998; Deurenberg et al., 2001).

ACKNOWLEDGMENT

The author is grateful to all individuals who participated in the study.

Chapter 252

FRAMING OBESITY AND UNDERNUTRITION AS PROBLEMS FOR GOVERNMENTS

Stanley Uljaszek*

Institute of Social and Cultural Anthropology,
Oxford University, UK

INTRODUCTION

The epidemiologies of obesity and undernutrition are conducted using standardized metrics in very regulated ways. From the 1950s, anthropometric measures have been used overwhelmingly as measures of social welfare in public health, economics and national statistics (Uljaszek and Komlos 2010). Their predominant use in most recent decades has been as proxies of human nutritional health (both under- and over-nutrition) and well-being (or lack thereof), as well as of physical productivity and health, in relation to measures of economic productivity, morbidity and mortality risk, where non-normative values of body size, usually height and weight, are interpreted as carrying risk. The procedures and protocols involved in these specific usages have been critiqued in various ways. For example, measurement in public health practice has been criticized as universalizing the human body when relating individuals to norms (Mol 2009) and of health to measurement (Yates-Duerr 2013). Issue has also been taken with the stigma that accompanies the measurement and medicalization of bodies (Rubin and Joseph 2013). Bodies are physical entities with economic, social and medical correlates, and the standardization of bodily measures of obesity and undernutrition have political and economic implications. This paper describes the now-historical process of nutritional assessment in public health anthropometry, and examines how public health reporting of obesity and undernutrition informs the discourse about nutritional health at governmental level. Examples are predominantly taken from India and the United Kingdom (UK).

NUTRITIONAL CLASSIFICATION USING ANTHROPOMETRY

In nutritional epidemiology, anthropometry can be used as a proxy for nutritional status, or as a measure of exposure to nutritional stress. Anthropometry became a proxy for nutritional status with the World Health Organization Technical Report 'Assessment of the Nutritional Status of the Community' (Jelliffe 1966). This became the standard text for relating anthropometry to nutrition and to social welfare in the subsequent two decades. The use of anthropometry in health and nutritional assessment has a formal scientific basis which stems from life insurance estimation of mortality prediction from the early twentieth century. The publication of 'standard height-weight' tables by the life insurance industry began with the *Medico-Actuarial Mortality Investigations of 1912* (Keys et al., 1972). These tables provided 'ideal' weight for ranges of height for use among insured adults in the United States (US) and Canada, according to sex and three categories of body frame. The first version of these standard tables, based on actuarial data relating to blood pressure (as a proxy for chronic disease risk), was brought into general use for assessing ideal body weight in the US in 1942/43 by the Metropolitan Life Insurance Company (Weigly 1984). Stature and weight continue to be the most widely used measures of nutritional status and disease risk at both extremes of body size. They give the simplest measure of attained frame, or skeletal size, and of soft tissue mass (Uljaszek 1997).

Obesity came to be measured with the body mass index (BMI), subsequent to its being described as the least-worst anthropometric measure of this phenomenon. The BMI had its origins in the Metropolitan Life Insurance Company tables. While body weight is always related to stature, the relationship is non-linear, and even direct correction for height does not remove this relationality completely. The height dependency of weight and stature-based measures of nutritional status was of concern for early epidemiological investigation of the health impacts of excess body fatness (Boe et al., 1957), because it made nutritional assessment difficult. After examining the height dependency of a number of weight-height indices and ratios, Boe et al., (1957) concluded that weight over height squared (W/H^2) gave the best height independent measure of relative weight. Subsequent studies in British, Cook Islander and US populations confirmed this view (Uljaszek 2017). In an analysis of the relative height independence of body fat prediction using different weight to height ratios, Keys et al., (1972) found generally much lower correlations of height with W/H^2 than with either weight over height (W/H) or weight over height cubed (W/H^3). These authors concluded that the ratio W/H^2 was clearly better than other measures of relative weight, and declared that this ratio be named the body mass index.

The cut-offs for ideal weight used in the Metropolitan Life Insurance Company tables are similar to those that were subsequently recommended for nutritional assessment using BMI by the Royal College of Physicians (1983) in the UK. The adoption of the closest whole-number BMI equivalent value to the very lowest and very highest boundaries for healthy weight in the Metropolitan Life Insurance Company tables by the Royal College of Physicians (1983) permitted ideal healthy weight to be determined without having to consider or measure frame-size (an undefined construct within these tables), simplifying anthropometric obesity assessment (James 2004). The BMI cut-offs of 18.5, 17.0 and 16.0 kg/m^2 were accepted for the assessment of different grades of adult undernutrition, or chronic energy deficiency, in 1992 (Shetty and James 1994), while BMI cut-offs of 25 and 30 kg/m^2

were accepted for classifying overweight and obesity by the World Health Organization (WHO) in 1997 (World Health Organization 2000). Alongside the acceptance of BMI as the measure of nutritional status of adults came the standardization of risk of mortality (Flegal et al., 2007) and morbidity (Campbell and Ulijaszek 1994; Canoy et al., 2007) at both lower and higher extremes of BMI.

At the upper end of population distribution, BMI shows strong associations with morbidity and mortality from number of chronic diseases and disorders for adults (World Health Organization 2000), and among a limited number of risk markers for chronic disease among adolescents (Bhargava et al., 2004). Figure 1 shows all-cause mortality according to BMI from the largest meta-analysis of BMI against mortality to date, the Prospective Studies Collaboration (2009), which includes nearly a million adults from 57 prospective studies.

Figure 1. All-cause mortality relative to body mass index, for 894,576 adults in 57 prospective mortality studies in industrialized countries (data from Prospective Studies Collaboration 2009).

Epidemiological studies relating BMI to mortality have methodological biases, however, including reverse causation and confounding by related factors such as smoking (Hu 2008). Epidemiological critiques of BMI include its inconsistent relationship with body fatness (Gallagher et al., 1996; Freedman and Sherry 2009), that it does not distinguish between potentially harmful fat in the liver and viscera (Carroll et al., 2008), and that it does not reflect health risk very well, except at the extremes (Lee et al., 2008).

BMI persists as a standard anthropometric measure of adult obesity, however, for both pragmatic and historical reasons. The BMI has been used for far longer than any other anthropometric measure, and was the first to be appropriated for the assessment of obesity rates in populations, after measures of stature and weight had been formalized for predicting mortality. Furthermore, there is no alternative measure of obesity that is collected nearly as systematically as the BMI. While waist circumference and waist hip ratio show as good, if not better, associations with mortality and morbidity risk (World Health Organization 2011), their possible adoption for international comparison would risk delegitimising programs and policies for obesity control that have used population monitoring of BMI as the measure of success or failure, at a time when adult obesity rates continue to rise (Stevens et al., 2012).

While the BMI has been universally adopted for obesity assessment, it does not have the best fit for all the purposes to which it has been assigned: individual classification; screening and monitoring for medical purposes; population monitoring for public health purposes; and econometric modelling. As the relationships between BMI, fatness and morbidity vary across populations (World Health Organization Expert Consultation 2004), there remain problems of how best to classify obesity using BMI. Relationships with morbidity and mortality vary according to the measure of obesity used, the population under investigation (be it of European, Asian, or African ancestry, whether it is young or old, male or female), and among the various classificatory boundaries that are used in obesity research and practice (World Health Organization 2000). In some Chinese (Li et al., 2002) and Asian (World Health Organization Expert Consultation 2004) populations, there is increased chronic disease risk at lower levels of BMI than among European populations (Li et al., 2002), and this has prompted recommendations for lower cut-offs for overweight and obesity for people of Asian origin (World Health Organization Expert Consultation 2004). At the other extreme, Pacific Islander populations generally have lower body fatness relative to lean body mass at any level of BMI, prompting the suggestion that higher BMI cut-offs should be used to assess overweight and obesity in these populations (Swinburn et al., 1999).

The BMI is also used to classify childhood obesity. This is more problematic than among adults, because of the variability in the growth rates of children both within- and between-populations which alters the normative range of BMI according to different normative bodily proportions at different ages, making fixed obesity cut-offs inappropriate. Age-specific cut-offs for childhood overweight and obesity that pass through adult classification cut-offs for overweight and obesity have been accepted for international use, however, using normative distributions that vary by age and sex (Cole et al., 2000). Evidence from systematic reviews of adult chronic disease subsequent to childhood obesity shows there to be significantly increased risk of premature mortality with child and adolescent overweight or obesity, as well as significantly increased risk of cardiometabolic morbidity (diabetes, hypertension, ischaemic heart disease, and stroke) in adult life (Reilly and Kelly 2011). Cardiovascular disease risk is, however, dependent on the tracking of BMI from childhood to adulthood, with the risk of raised blood pressure in adult life being highest among those at the lower end of the BMI scale in childhood, but overweight in adulthood (Lloyd et al., 2010).

In the formalization of BMI for international use for the measurement of obesity (World Health Organization 2000), the overarching aim was to provide simplicity for assessment and monitoring of obesity world-wide. Standardized classification of obesity was accepted by the World Health Organization (2000) because it claimed that it allowed meaningful comparisons within and between populations, the identification of individuals and groups at increased risk of morbidity and mortality, the identification of priorities for intervention at individual and community levels, and a firm basis for evaluating interventions.

Reporting Obesity

Both height and BMI are positively associated with socioeconomic status (SES) in India (Som et al., 2014), and a positive secular trend in increased body size has been observed in some populations there (Khanna and Kapoor 2004). There has also been an increase in

obesity rates among children and adolescents (Mistry and Puthussery 2015) and among adults in most Indian States (Bharati et al., 2007). While there has been an emergence of the dual burden of undernutrition and obesity across much of India (Bharati et al., 2007) (Table 1), such dual burden does not exist yet among those of low SES, suggesting that transition towards energy-dense, nutrient-poor diets and low physical activity (Popkin 2002) in India is at an early stage (Subramanian et al., 2009).

Table 1. Percent obesity, overweight and undernutrition, India, adult women
(data from Bharati et al., 2007)

State	Obesity (BMI>30)	Overweight (BMI 25-30)	Undernourished (BMI<18.5)	Combined burden
Punjab	9.0	21.1	16.4	46.5
New Delhi	8.9	24.1	12.2	45.2
Goa	4.4	16.7	26.8	47.9
Gujarat	4.3	11.3	36.3	51.9
Maharashtra	4.1	12.6	33.2	49.9
Kerala	3.8	17.0	18.0	38.8
Haryana	3.7	12.3	25.6	41.6
Himachal Pradesh	3.3	13.2	26.5	43.0
Jammu	3.3	11.7	24.7	36.4
Tamil Nadu	3.1	13.4	26.1	42.6
Karnataka	2.8	10.3	38.2	51.3
All India	2.6	9.4	31.2	43.2
Sikkim	2.3	12.1	10.9	25.3
West Bengal	2.3	10.3	37.9	50.5
Andhra Pradesh	2.2	9.9	36.5	48.6
Tripura	1.8	6.5	34.5	42.8
Uttar Pradesh	1.5	5.8	34.7	42.0
Rajasthan	1.4	5.0	35.2	41.6

Figure 2. Percentage difference in obesity rates between the least (1st decile) and most (10th decile) deprived Index of Multiple Deprivation Local Authority Districts based on school postcode, England, between 2007/8 and 2013/14, children aged between four and five years, and between ten and eleven years (data from Public Health England 2016).

In the UK, various surveys from the start of the nineteen hundreds onwards show there to have been a secular trend towards increased height and weight until the 1970s (Floud et al., 1990), followed by emergent overweight and obesity among children (Chinn and Rona 2001) and adults (Garrow 1978) especially among those of lower SES (Ulijaszek 2014). In the UK and other high income countries (HICs), rates of childhood overweight and obesity appear to have plateaued (Wabitsch et al., 2014), although this effect has been shown mostly in studies of short duration (Visscher et al., 2015). Where rates of childhood and adolescent obesity have been shown to plateau, socioeconomic inequalities in obesity rates have persisted or increased (Ulijaszek et al., 2016), as in the US (Frederick et al., 2013) and the UK (Stamatakis et al., 2010). Data that is taken to be nationally-representative in England show this effect between 2007 and 2015 (Figure 2) (Public Health England 2016), expressed as percentage differences in obesity rates between the least and most deprived Local Authority Districts.

Anthropometry as Evidence in Policy Making

The most basic form of evidence for policy on nutritional status is nationally-representative data across administrative units and across time. The use of the concept of human capital, which includes adult height, educational achievement, income and birth weight, expresses the economic logics that underpin the intervention, that good nutrition is a prerequisite for economic development (Bryce et al., 2008). Nutrition came to the policy forefront in India in the 1990s, with the National Nutrition Policy (1993) and the 1995 National Plan of Action on Nutrition (Mohmand 2012). With respect to undernutrition in India, two data sources for nationally-assessed nutritional status for policy purposes have predominated. The first of these, the National Family Health Survey (NFHS) is collected periodically by the International Institute for Population Sciences, and is a large-scale, household level sample survey conducted across India that provides information on the main outcome indicators of malnutrition - underweight, stunting and wasting, along with a host of other health indicators. This survey has been repeated periodically, with NFHS-1 having been conducted in 1992-93, NFHS-2 in 1998-99 and NFHS-3 in 2005-06. The second of these, the Integrated Child Development Services (ICDS) scheme of the Ministry of Women and Child Development carries out regular monitoring of the weight of children under the age of 6 years, among its many functions. Anthropometric nutritional assessment has been used in both NFHS and ICDS surveys to identify the regions of India with highest burdens of undernutrition. Obesity has never been measured or reported systematically using the NFHS or ICDS surveys. However, at the national level, obesity policy in India is observed in the reporting of data to the WHO and some compliance to WHO obesity policy (World Health Organization 2000; 2016).

As with measures of anthropometric undernutrition, the measurement of obesity rates and its reporting provides evidence for the existence of population obesity and its changing patterns across time, and for identifying possible governmental interventions against it. Speaking to the importance of data collection for childhood obesity policy, Nathan et al., (2005) assert that policy can be made in the absence of strong research evidence, but where powerful and competing groups contest possible policy options, the evidence required needs

to be substantial. Nationally-representative data on obesity rates are often illustrated using obesity prevalence maps, where obesity rates are shown according to administrative units within-nation. Figure 3 shows such a map for England, according to Local Authority. Such maps have been used to illustrate inequalities in rates of obesity according to social class, gender, ethnicity and geography across the country and within cities. By combining categories, such mapping has also been used to demonstrate regional differences due to variations in proportions of the population of low SES across the country and according to levels of deprivation (Moon et al., 2007).

Figure 3. Obesity rates in adults, England 2012.

Epidemiological data collection and reporting, and the use of obesity epidemiology in econometric modelling of the impacts of obesity, are usually starting points for state-led obesity interventions (Malik et al., 2013). The spur to policy action by most nation-states is overwhelmingly economic (Ulijaszek 2017). The most persuasive political arguments usually involve framing obesity as a significant burden to the economy and health service, usually through costs to employers, its medical management, and of the chronic diseases associated with it (Wang et al., 2011). In the UK, obesity has also been compellingly depicted as a drag on the economy, both in terms of lost productivity and in terms of costs to state-provided health care provision (House of Commons Health Committee 2004). Obesity assessment from annual data collection of adult heights and weights by Health Survey for England (HSE) was initiated in 1993, while the National Child Measurement Programme (NCMP) was set up to monitor childhood obesity in 2007 by the National Obesity Observatory (NOO). The NCMP continues as an annual programme of measurement of heights and weights of the vast majority of children in the first and final years of State-funded primary schools in England.

Both HSE and NCMP obesity monitoring hold UK National Statistics status in the same way that the reporting of births, deaths and marriages does.

Figure 4. Distribution of self-reported health scores (the higher the healthier) according to obesity (according to body mass index) and chronic illness, after adjusting for age, gender, and frequency of health service utilization, United Kingdom (data from Doll et al., 2000).

The categorization of obesity as a disease in the US and by the WHO has aimed to raise the profile of obesity for medical intervention, but this categorization continues to be contested (Rich et al., 2011). Obesity as risk factor also has a place in the framing of health policy, because it sits among other risk categories such as smoking, unhealthy diet, and physical inactivity for chronic disease onset and progression (Erlichman et al., 2002). Categories of risk have ambivalent status in policy-making, however. For example, smoking damages health and human productivity, but its taxation gives a steady stream of reliable income to governments (Chaloupka and Warner 2000). Similarly, unhealthy diet is damaging, but the food industry, which supplies uncontaminated and affordable food to large populations, primarily seeks to continue its operations without undue regulation (Uljaszek and McLennan 2016).

DISCUSSION

Undernutrition reduces work capacity and productivity among adults, reducing earning capacity and aggravating poverty, as well as enhancing mortality and morbidity among children (Anish et al., 2013). Furthermore, poverty in childhood increases risk of non-communicable diseases in adult life (Conroy et al., 2010). While nutrition policy in India remains focused on undernutrition, the collection of nationally-representative data on anthropometric nutritional status has highlighted the decline in nutritional stunting, if not of wasting (Mohmand 2012), and the rise in obesity in more recent years (Bharati et al., 2007). The emergence of the dual burden of both undernutrition and obesity across the nation, even

if not yet located among those of low SES (Subramanian et al., 2009), has led to calls for national nutrition policy that can address this new problem (Mohmand 2012). The economic costs of obesity to India include those of lost productivity, but increasingly the costs of treating the rapidly rising rates of type two diabetes (Mohan et al., 2007).

While BMI cut-offs for obesity classification are viewed as being meaningful according to epidemiological analyses (World Health Organization Expert Consultation 2004), they can differ from individual health perceptions of health and well-being. For example, self-reported health status of adults in the UK among obese people who have not experienced chronic disease is similar to that of people categorized as being of normal weight (Figure 4), with respect to physical function, bodily pain, general health and vitality, social functioning and mental health (Doll et al., 2000).

Obesity may not be perceived as a problem among those carrying excess body fatness prior to experiencing any of the chronic diseases associated with it. Anthropometric measurement of obesity has been critiqued by social scientists for its medical distancing of the individual experience of living with a fat body (Yates-Doerr 2013), whether or not such experience has been linked to chronic disease experience. It has also been viewed by social scientists as a way of universalizing the human body by governmental institutions through epidemiological reporting, by relating individuals to norms and health to measurement (McCullough and Hardin 2013). Brewis et al., (2011) note the stigma that accompanies the measurement and medicalization of fat bodies, while Puhl and Brownell (2001) have reported the widespread stigma attached to obesity. The stigma attached to undernutrition has also been reported to be a barrier to the uptake of medical treatment and nutritional rehabilitation by mothers and young children in Pakistan (Mull 1991), Tanzania (Howard and Millard 1997) and Kenya (Bliss et al., 2016).

The policy uses of anthropometric nutritional status combine it with other nationally-oriented data such as birth, death, disease and economics. The reported numbers and their use in policy are a long way from the individuals that data collection is designed to serve. Undernutrition in India persists, and is framed as an object for policy intervention, as good nutrition is seen as a prerequisite of economic development in low income countries. In HICs, obese people are shamed and obesity is viewed as a drag on the economy. Through reporting nutritional status, ideal citizen-bodies are constructed through growth and body size references, not in relation to individual well-being, but in relation to the best economic functioning of the State. Neoliberal politics forces ideal body citizenship on the individual, however, despite individuals and populations being urged, in the case of India, to develop (Berg 1973), and in the case of the UK, to consume (Ulijaszek and McLennan 2016). Thus measuring and reporting nutritional status and obesity raises questions about differing forms of biological citizenship.

OBESITY

Concept and Epidemiology

Overweight and obesity are defined as abnormal or excessive fat accumulation that may impair health. Body Mass Index (BMI) is a simple index of weight-for-height that is commonly used to classify overweight and obesity in adults. It is defined as a person's weight in kilograms divided by the square of his height in meters (kg/m²) i.e., $BMI = Wt \text{ in Kg} / Ht \text{ in m}^2$. The WHO defines overweight as BMI greater than or equal to 25kg/m² but less than 29.9kg/m²; and obesity as BMI greater than or equal to 30 kg/m²(WHO, 2017a). Though for the Asian population a BMI of 27kg/m² is equivalent to a value of 30 kg/m² in other groups (WHO, 1998). Overweight means excess in body weight and may be the resultant of higher lean body mass (muscle, bone, or body water content) but not only because of the weight of the total body fat. Obesity, on the other hand, denotes the presence of excess body fat. All obese persons are overweight, but all overweight persons are not necessarily obese as the excess body weight may arise from the lean body mass as well (Mandal, 2010). The adverse health outcomes associated with overweight and obesity range from an increase risk of mortality to a non-fatal debilitating disease (WHO, 1998). Obesity therefore is a medical

condition of excess of body weight due to the accumulation of fat leading to an adverse effect on health, reduced life expectancy and/or increased health problems.

Genetics, environmental, metabolic, behavioral, and socio-cultural factors play major roles in pre disposing a person to obesity. Genetics plays an important role in shaping the BMI status of an individual. How much variation in weight gain among individuals can be accounted for by genetic factors? Obesity frequently begins in childhood and generally the obese parents may likely have overweight children. Familial association is not a proof of genetic inheritance for families having shared eating and exercise habits. However, familial association cannot be considered as a proof of genetic inheritance-as families share common lifestyle pattern such as dietary pattern and exercise habit. It is claimed that about 200 different genes or loci have been linked with controlling obesity in humans (Lau, 1999). However, the pattern of inheritance of obesity suggests that the effect is polygenic, with each variant of many different genes making a small difference in effect (Sorensen and Soren, 2001). Apart from this, both age and sex have role to play in causing obesity. Many studies have shown that excessive weight gain leading to overweight and obese condition usually develops slowly through adulthood and most weight gain occurs between the age of 25 to 44 years. Again females are more prone to obesity as compared to males because of their anatomical structure and physiological features such as not losing the weight they have gained during pregnancy and gaining body weight by about 12-15 pounds with the attainment of menopause.

When we talk of the environmental factors, it encompasses the totality of the surrounding in which we find ourselves. Gaining excessive body weight leading to overweight and obese condition is a long term process brought about by a number of socio-cultural practices and habits. The way of eating during childhood can affect the way one eats as adults. The way of eating over many years becomes a habit. What we eat, when we eat, and how much we eat is certainly a determinant of weight gain and obesity. Certain habits such as eating more food than our body can use, drinking too much alcohol, not getting enough exercise, quit smoking, stress, anxiety, feeling sad, or not sleeping well are said to be important contributory factors for gaining excessive weight and obesity. At the same time certain medical problems or treatments cause weight gain including underactive thyroid gland (hypothyroidism), medicines such as birth control pills, antidepressants, and antipsychotics.

On the whole, the potential contributory factors culminating to global increase in overweight and obesity in the past three decades are changing lifestyle patterns such as increase in calorie intake, changes in the composition of diet, decreasing levels of physical activity, and changes in the gut microbiome as well (Bleich et al., 2008, Astrup and Brand-Miller J, 2012, Drewnowski and Popkin, 1997, Popkin, 2001, Blair, 2013). Though there are multiple causal factors associated with the rise in obesity in developing countries, the two most important factors are urbanization and globalization (Benjamin Caballero, 2007, Nanan, 2002). In short, urbanization and globalization have resulted in modernization which is the key causal factor for overweight and obesity. The urban lifestyle as compared to the rural setting has difference in energy balance as a result of difference in energy intake and energy expenditure. The energy consuming manual labor, long walks to work places for earning their livelihood and also procuring their subsistence typical of rural areas are replaced by sedentary lifestyle characterized by mechanized system of transportation, machineries and desk or sidewalk job. In short the urban lifestyle demands much lower energy expenditure as compared to the rural way of living in rural settings. On the other hand, the urban dwellers

consume more energy dense food readily available in the urban market in contrast with low energy expenditure thus culminating to gradual weight gain. Whereas the reverse is the condition of the rural dwellers as they expend more energy and consume low nutrient and less energy content food conditioned by low economy on one hand, and unavailability of energy dense food on the other. As such the children in rural areas cannot achieve normal growth thus resulting into underweight adults. As economic development bring some characteristics of urban lifestyle to rural communities, these populations also begin to show increasing rates of obesity, particularly among women these days (Mendez, 2005). Unhealthy dietary habits and less physical activity are likely to endure thereby increasing the risk among today's youth for obesity and chronic diseases in future unless the public health initiatives are designed to be multilevel and take into consideration the multiple correlations that influence behaviour surrounding dietary intake and physical activity (Sandra et al., 2012).

Obesity is a major risk factor for cardiovascular disease (CVD) and Type 2 diabetes mellitus (DM) and in the presence of other risk factors for non-communicable diseases (NCDs) such as smoking, hypertension, elevated blood cholesterol and it has a multiplicative effect (Thorkhild et al., 2000, Blackburn and Luepker, 1986). A number of literatures reveals that the consequences of obesity include various diseases and morbid conditions which increase the chances of mortality such as Diabetes, Coronary Heart Disease, Peripheral Artery Disease, Stroke, Hypertension, Hyperlipidemia, Arthritis, Obstructive sleep apnea, Pulmonary disease, PCOS/infertility, Dysmenorrhea, Pregnancy complications, Gallbladder disease, Skin infections, Urinary incontinence, Depression, Eating disorders, social stigma, Cancers: breast, endometrial, colon, prostate, gallbladder, kidney, esophagus, etc.

Global Scenario

The worldwide prevalence obesity has nearly tripled since 1975. In 2016, more than 1.9 billion adults, 18 years and older, were overweight. Of these over 650 million were obese. As many as 39% of adults aged 18 years and above were overweight in 2016, and 13% were obese. Most of the world's population live in countries where overweight and obesity kill more people than underweight. As many as 41 million children under the age of 5 were overweight or obese in 2016. Over 340 million children and adolescents aged 5-19 were overweight or obese in 2016 (WHO, 2017a). Obesity has reached pandemic proportions globally with at least 2.8 million people dying each year as a result of being overweight or obese. Once associated with high-income countries, obesity is now also prevalent in low- and middle-income countries (WHO, 2017b). It has been reported that number of overweight and obese individuals increased from 857 million in 1980, to 2.1 billion in 2013. The worldwide prevalence of overweight and obesity combined rose by 27.5% for adults and 47.1% for children between 1980 and 2013 (Emmanuela et al., 2014).

It is a well-established and known fact that the prevalence of overweight and obesity is overwhelmingly increasing globally during the last few decades. Several studies have revealed that it has become a global pandemic issue (Roth et al., 2004, Swinburn et al., 2011, Popkin and Adair, 2012). In 2010, a worldwide estimate reveals that overweight and obesity resulted in 3.4 million deaths, 4% of years of life lost, and 4% of disability-adjusted life-years (Lim SS, 2010), thus resulting in future fall of life expectancy.

**Top 10 Countries with most obese population size in order of ranking
as on July 1st, 2017**

1.	US	–	109,342,839
2.	China	–	97,256,700
3.	India	–	65,619,826
4.	Brazil	–	41,857,656
5.	Mexico	–	36,294,881
6.	Russia	–	34,701,531
7.	Egypt	–	28,192,861
8.	Turkey	–	23,819,781
9.	Iran	–	21,183,488
10.	Nigeria	–	20,997,494

Source of Data; Renew Bariatrics, 2017.

Getting little bit acquaintance with the numerical figure, the total population of the world is 7,505,257,673 while 774,000,000 of them are obese thus constituting almost 10.5%. New research suggests that, there are about 775 million obese people in the world including adults, children, and adolescents. Our research suggests that, there are nearly 650 million obese adults on the planet, as defined as a body mass index (BMI) over 30. There are also about 125 million obese children and adolescents in the entire world according to a BMI over 30 kg/m². The majority of the obesity on the planet resides in a few countries. The following data will reveal top ranking status in relation to obesity parameter.

**Top 10 Countries with most obese population percentage in order
of ranking as on July 1st, 2017**

1.	Cook Islands	–	50.80%
2.	Palau	–	47.60%
3.	Nauru	–	45.60%
4.	Samoa	–	43.40%
5.	Tonga	–	43.30%
6.	Niue	–	43.20%
7.	Marshal Islands	–	42.80%
8.	Qatar	–	42.30%
9.	Kiribati	–	40.60%
10.	Tuvalu	–	40.30%

Source of Data; Renew Bariatrics, 2017.

**Top 10 Countries with least obese population percentage in order
of ranking as on July 1st, 2017**

1.	Central African Republic	–	5.10%
2.	India	–	4.90%
3.	Uganda	–	4.90%
4.	Somalia	–	4.60%
5.	Democratic Republic of the Congo	–	4.40%
6.	Niger	–	4.30%
7.	Eritrea	–	4.10%
8.	Ethiopia	–	4.00%
9.	Rwanda	–	4.00%
10.	Bangladesh	–	3.60%

Source of Data; Renew Bariatrics, 2017.

The health risks associated with rising obesity being well aware universally; member states of WHO have introduced a voluntary target to stop the rise in obesity by 2025, (WHO 66.10, 2013) and also to address the issue by regular monitoring and assessing the trend in the prevalence of overweight and obesity in all populations (Swinburn BA, 2008, Cole TJ et al., 2000, Gortmaker SL et al., 2011).

Substantial rise in the prevalence of overweight and obesity with marked variations and distinct regional patterns across countries has been observed in the past three decades. Though the trend of increasing overweight and obesity is expected to continue in developing countries, as suggested by the fact that two in three of the world's obese people live in such countries, it has started gradually attenuating in the past 8 years in developed countries where increase in obesity that began in the 1980s (Emmanuela et al., 2014).

Excess adiposity/body weight is now widely recognized as one of today's leading health threats in most countries around the world and as a major risk factor for type 2 diabetes, cardiovascular disease, and hypertension (Fogel, 1986). Until the last decades of the 19th century, developed countries were still struggling with poverty, malnutrition, and communicable diseases. These health problems were considered a major cause of low industrial productivity (Fogel, 1997).

Until relatively recently, obesity was considered a condition associated with high socio-economic status. Indeed, early in the 20th century, most populations in which obesity became a public health problem were in the developed world primarily the United States and Europe. In more recent decades, available data shows that the most dramatic increases in obesity are in developing countries such as Mexico, China, and Thailand (Popkin and Gordon, 2004). The global nature of the obesity epidemic was formally recognized by a World Health Organization consultation in 1997 (WHO, 2004).

Indian Scenario

According to a study published in the noted journal *Lancet*, India is just behind the US and China in this global hazard list of top 10 countries with highest number of obese people (Emmanuela, 2014, Sharma, 2014)). Report of the first phase of the National Family Health Survey (NFHS-4) 2015-16 shows that among the males the highest obesity is observed in the population of Andaman and Nicobar Union territory, followed by Goa, Andhra Pradesh, Sikkim, Punjab, Dadra & Nagar Haveli, Daman and Diu, Puducherry, Mizoram and Telangana in order of ranking. As for female population is concerned, the top 10 ranking States and Union territories are Chandigarh, Lakshadweep, Andhra Pradesh, Puducherry, Delhi, Goa, Punjab, Telangana, Tamil Nadu and Daman and Diu. The report also clearly reveals that in all the states and Union Territories, the number of obese women almost doubled that of males. On comparing the report of NHFS 4 with that of NFHS 3 and NFHS 2, the percentage of overweight and obese population has risen substantially in India during the last one and a half decade among the female population. The overweight and obese population increased by almost 60% and 80% respectively among the females during the said period. As for male population is concerned, a marked increase of almost 90% for overweight population and 400% for obese population is seen during the last decade.

**Top 10 States/Union Territory of India with most obese population
percent in order of ranking as for 2015-2016**

Ranking	Most obese male population		Most obese female population	
	State/ Union Territory	Percentage	State/ Union Territory	Percentage
1	Andaman & Nicobar	8.1	Chandigarh	14.9
2	Goa	7.7	Lakshadweep	14.6
3	Andhra Pradesh	7.7	Andhra Pradesh	10.3
4	Sikkim	5.9	Puducherry	10.2
5	Punjab	5.1	Delhi	10.1
6	Dadra & Nagar Haveli	4.8	Goa	9.9
7	Daman & Diu	4.8	Punjab	9.2
8	Puducherry	4.8	Telangana	8.6
9	Mizoram	4.8	Tamil Nadu	8.3
10	Telangana	4.8	Daman & Diu	8.1

Source: NFHS data.

**Top 10 States/Union Territory of India with least obese population
percent in order of ranking as for 2015-2016**

Ranking	Least obese male population		Least obese female population	
	State/ Union Territory	Percentage	State/ Union Territory	Percentage
1	Jharkhand	1.2	Meghalaya	1.7
2	Nagaland	1.3	Jharkhand	2.1
3	Bihar	1.3	Assam	2.1
4	Meghalaya	1.4	Bihar	2.2
5	Chhattisgarh	1.4	Tripura	2.4
6	Uttar Pradesh	1.6	Chhattisgarh	2.4
7	Madhya Pradesh	1.6	Nagaland	2.7
8	Tripura	1.7	Arunachal Pradesh	2.9
9	Assam	1.7	Madhya Pradesh	3.1
10	West Bengal	1.8	Rajasthan	3.3

Source: NFHS data.

While considering the Union territory and State-wise distribution of least obese population among the males, it is observed that Jharkhand has the least obese population followed by Nagaland, Bihar and Meghalaya. As for female population, the least is observed in Meghalaya followed by Jharkhand, Assam and Bihar. Interestingly almost all the States of North East India has a very high percentage of normal BMI ranging from 66.4% to 78.4% among the males and 65% to 75.8% among the females.

According to World Health Organization (WHO), many low-and middle-income countries are now facing a double burden of disease which means that while they continue to struggle with infectious disease and under-nutrition, they are also experiencing a sharp rise in non-communicable disease risk factors such as obesity and overweight. Several research findings reveals that obesity is rising during the last few decades and NFHS, 1998-199, 2005-2006 and 2015-2016 data confirms the trend. This could be a result of lifestyles changing over the years and is a confounder of a large number of non-communicable diseases,” said Sutapa Agrawal, an epidemiologist with Public Health Foundation of India, a public-private initiative involving Indian and international academics, and state and central governments (Live Mint, 2016).

**Top 10 States/Union Territory of India with Normal BMI population
percent in order of ranking as for 2015-2016**

Ranking	Normal BMI male population		Normal BMI female population	
	State/ Union Territory	Percentage	State/ Union Territory	Percentage
1	Meghalaya	78.4	Meghalaya	75.7
2	Nagaland	74.7	Arunachal Pradesh	72.7
3	Mizoram	71.9	Nagaland	71.6
4	Arunachal Pradesh	71.1	Mizoram	70.6

Strategy for Management and Prevention

It is globally known fact that, excessive weight gain carries significant high mortality health risks diseases - cancers, diabetes, heart diseases and strokes. And it is not a time to keep watching the menace, allowing ourselves to be controlled by a “pandemic” but to address it through timely intervention. Swinging back the pendulum for achieving a healthier bodyweight and desirable BMI level is the need of the hour so as to prevent from undesirable morbid condition. For the last few decades, numerous scientists and organizations around the world have worked tirelessly to address the issue of obesity though with only modest success. Continuous efforts are needed for improving and standardizing strategic planning for fighting this pandemic issue.

Source of Data: NFHS.

Figure 1. BMI trend of Indian women population observed from 1998 to 2016.

One of the most effective steps is changing the “obesogenic” environment toward reducing obesity. Reducing the excess caloric intake and equalizing it with energy expenditure by way of increasing physical activities is one of the best ways to fight obesity. There is no single or simple solution to the obesity epidemic. So this complex problem can be

addressed by a multifaceted approach. Policy makers, state and local organizations, business and community leaders, civil society organizations, educational institutions, childcare and healthcare professionals, and individuals must put their heads together and work together to create an environment that supports a healthy lifestyle. To reverse the obesity epidemic, community efforts should focus on supporting healthy eating and active living in a variety of settings. Learn about different efforts that can be used in early childhood care, hospitals, schools, and food service venues (CDC, 2015).

Source of Data: NFHS.

Figure 2. BMI trend of Indian male population observed from 2005 to 2016.

There are several ways by which state and local organizations and NGOs and Government allied system can create a supportive environment and awareness to the general public to promote healthy living behaviours that prevent obesity. The etiology of obesity is multifaceted; there are factors from multiple contexts, and interactions between factors that led to obesity are not yet well understood (Jhan et al., 2010). Indeed, a comprehensive approach is needed to potentially reverse the global pandemic of obesity (Jhan et al., 2010, Reed, 2011). Globally, there is also solid consensus on the steps taken up to stop the obesity epidemic which were outlined in the Food and Agriculture Organization/World Health Organization global strategy for the prevention of diet-related chronic diseases (WHO, 2003). Researchers and medical scientists can also play major roles by researching the epidemiology and etiology of obesity in order to fight this pandemic issue.

Chapter 254

OBESITY AND SYNDROME X

Anup Adhikari*

Anthropometrica, Toronto, Canada

Metabolic Syndrome is a group of health conditions like obesity, high blood pressure, high blood sugar, high serum triglycerides and low high density lipoprotein (HDL) level. This combination is also known as Syndrome X. Hence, metabolic syndrome is a group of risk factors but not a disease. The main sign of metabolic syndrome is obesity. Obesity goes together with unhealthy level of cholesterol, high blood pressure and excess blood sugar (Ganong 2008).

Obesity turned into epidemic and became a public health challenge throughout the world. In past few years, the prevalence of obesity has been increased significantly across the world no matter whether it is a developed or developing or underdeveloped country. According to World health Organization, more than 1.9 billion adults aged 18 or older were reported overweight. Of these, over 650 million were obese. 39% of adults aged 18 year and over were overweight and 13% were obese in 2016 according to WHO report. 41 million children under the age of 5 were overweight or obese, whereas 340 million children and adolescent aged 5-19 were overweight or obese in 2016. Once considered to be a high-income country problem, overweight and obesity are now on the rise in low, and middle income countries also, particularly in urban settings (WHO 2012; Adhikari 2014; WHO 2018).

Obesity is a health problem associated with accelerated atherosclerosis and increased incidence of gall bladder and other diseases like type two diabetes. Not only that, recent studies reported death from many kinds of cancer in obese people. The causes for obesity in general population are due to multiple reasons. The primary cause of obesity is excess intake of energy over energy expenditure. The other causes are genetic and decrease sensitivity to leptin. Genetic factors are also responsible for obesity in some cases and causes excessive accumulation of body fat. Though, genetic tendency does not necessarily cause obesity, but it helps to accumulate more fat in right environment for the genetically susceptible individuals. A faulty gene or obese gene inside the fat cell produce Leptin, which after entering into blood, stimulates the hypothalamic area which controls the appetite and metabolism, causing

* Corresponding Author's Email: dranupadhikari@yahoo.com.

fat accumulation. But genetic factors are not the reason for worldwide obesity epidemic. Instead, misbalance between energy intake and energy expenditure is the main reason for obesity (Frisch et al. 1987; Frisch et al. 1989; Bouchard et al. 1990; Stager & Halter 1995; Bouchard 1997; Fogelholm et al. 1998; Elchebly 1999).

While expressing body composition and related health risks of excessive body fat, three terms are used -over weight, overfat and obese. There is a confusion over the meaning of precise terms for overweight, overfat, and obese. Each term has a different meaning when using in different circumstances. Still there is a need to make a distinction between overweight, overfat and obese during interpretation. In most cases the term overweight is meant for an overfat condition even in the absence of accompanying body fat. Within this context, obesity then refers at the extreme of overweight continuum. This is precisely the frame of reference which is used to define the body fat range by means of BMI. Thus, weight-for-height at a given age has provided the most suitable index to express body fat and accompanying health risks. However, the overweight refers to a body weight greater than the average for stature. Overweight is not always due to presence of fat, it may be due to presence of muscle mass. For example, man with more muscle mass will be overweight (male power athletes). The overweight condition may or may not go with glucose intolerance, insulin resistance, dyslipidemia, and hypertension (e.g., physically fit overfat men and women). But obesity or overfat condition will go with one or all of the following components of the syndrome X like insulin resistance, glucose intolerance, dyslipidemia, type 2 diabetes, hypertension, high serum triglycerides, elevated plasma leptin concentrations, increased visceral adipose tissue, and increased risk of coronary heart disease and cancer etc. Syndrome X is related with excess body fat not with excess body weight which is due to more muscle mass or having more mesomorphic component which was revealed by different studies. Person may be overweight or overfat but does not have the syndrome X sign and symptoms. Men above 20% and women above 30% may be considered as overfat but it may vary population to population.

There are two types of regional fat distribution. When fat deposits more in abdominal area causing obesity, is called Android type obesity. This is particularly internal visceral deposition which is due to catecholamine secretion resulting lively lipolysis of tissues. The other type of deposition where fat deposit more in gluteal and femoral region, is called as Gynoid type obesity. The Android type obesity which causes deposition of more fat in central region causes heart disease. For men, percentage of visceral fat increases gradually with age, whereas in women, it starts at the onset of menopause. In Android-type obesity where fat deposits centrally, results risk of hyperinsulinemia, glucose intolerance, type 2 diabetes, hypertriglyceridemia, endometrial cancer, hypercholesterolemia and negative altered lipoprotein profile, hypertension, and atherosclerosis. The waist to hip ratio can be considered as an indicator of health risk when the ratio exceeds 0.80 for women and 0.95 for men. Excess fat distribution in abdomen area also increases the risk for colorectal cancer. Thus Android -type obesity has a greater risk than gynoid-type obesity where fat deposit at thighs and buttocks instead of central region of the body.

Less energy expenditure than energy intake causes fat accumulation which results body weight gain. Similarly when energy expenditure is more than energy intake causes weight loss. Thus three ways can reduce body weight. If calorie intake goes down below the daily energy requirement by dieting, it causes weight loss. Similarly, when energy expenditure exceed than normal calorie intake by means of physical activities causes weight loss. One

more method, when reducing the daily calorie intake by dieting but increasing the daily energy expenditure by means of physical activities, causes weight loss.

Weight loss through dietary restriction for short period results more water and carbohydrate loss per unit weight loss than the loss of fat. But dieting by low carbohydrate for long period may have some adverse effects which are dehydration, frequent urination, muscle cramp, constipation, irregular menstruation etc. Studies reveal that long term maintenance of weight loss through dietary restriction could be followed by return of lost weight within few years once restriction is stopped. Though careful dieting results weight loss but it may cause loss of Fat Free Mass (FFM), lethargy, possible malnutrition, and depressed resting metabolism (Miller 1999; Jeffrey et al. 2000; National Task Force 2000).

The best way to reduce body weight or excess body fat is regular physical exercise. Increased physical activity with dietary restriction causes weight loss more effectively than long term caloric restriction alone. Aerobic exercise and resistance training are more effective for weight loss for obese population. Aerobic exercise reduces the amount of fat and resistance training increase muscle strength and muscle mass which ultimately increase Fat Free Mass (FFM). Studies revealed that 40 -50 min aerobic exercise comprises of running and jogging for five days a week for 3-4 months significantly reduces excess body fat for obese population (vanEtten et al. 1994; Kraemer et al. 1995; Owens et al. 1999). Active children gain more Fat Free Mass (FFM) and loss total fat compare to their inactive children. Similarly, adolescent males who do regular aerobic exercise, reduce total body fat significantly faster than their sedentary counterparts.

Aerobic exercise or endurance run very effective for the obese population to reduce excess body weight by burning excess body fat. Endurance run or aerobic exercises increase the aerobic metabolism where energy releases from the breakdown of carbohydrate and fat in the presence of oxygen.. Walking, jogging, running, biking, aerobic dances are the best examples of aerobic exercises which help the obese people to reduce fat as well improve cardiovascular fitness, reduce syndrome X risk factors. While walking, it is recommended for more than one hours walking with fast pace for 3-4 days in a week. If someone wants jogging, it is recommended to walk first, then after few weeks start jogging and then running gradually. Biking is also very good aerobic exercise. Obese people also can join with aerobic dance program in a gymnasium which is also an effective aerobic exercise for reducing excess body fat. Dancing is also an effective aerobic exercise. But before starting any exercise program, one must see the family physician if they already have syndrome X rich factors and should take the physicians advice before any aerobic exercise program.

To fight against the obesity epidemic, promotion of aerobic exercise is needed which will increase the total energy expenditure significantly and regularly rather than increase exercise intensity. An obese person can expend more calories if he or she starts with slow walking or jogging with simply extending for long duration as duration of exercise significantly affects fat loss. It is important to note that recommended aerobic exercise should be minimum 3 days in week to have a good impact on fat loss. Regular aerobic exercise delay lean tissue loss, while resistance training increases Fat Free Mass. To combat against obesity and syndrome X, aerobic exercise should be popularized more and more across the world.

Chapter 255

SYNDROME X: SOME COMMON DETERMINANTS WORLDWIDE

Mithun Das^{1,*} and Kaushik Bose²

¹Department of Anthropology, Sree Chaitanya College, Habra, West Bengal, India

²Department of Anthropology, Vidyasagar University, Midnapore, West Bengal, India

Syndrome X or Metabolic Syndrome (MetS) is defined as a constellation of several cardiovascular disease (CVD) risk factors including genetic and environmental factors that is responsible for ultimate predisposition of the disease (Grundy 2005). The constellation of centrally distributed obesity; decreased high density lipoprotein cholesterol (HDLc); elevated triglycerides; elevated blood pressure and hyperglycemia is known as the MetS. Persons with MetS are at twice the risk for CVD compared with those without the syndrome. It further raises the risk for type 2 diabetes mellitus (T2DM) by about five-fold (Zimmet et al., 2005; Grundy et al., 2008). This chapter will highlight the common determinants/factors associated with Syndrome X worldwide, which include: Family history of chronic diseases, Physical Inactivity, Dietary Intake of Fatty Acids, and Epigenetic Modifications.

FAMILY HISTORY OF CHRONIC DISEASES

Most of the common chronic diseases are the result of interactions between multiple genetic variants and environmental vis-à-vis lifestyle factors. Although there have been significant advances in the last decade in the understanding of our genome, there are certain limitations in epidemiological and analytic approaches to studying the effects of chronic diseases. Family history has been shown to be a risk factor for a majority of chronic diseases of public health significance, including Syndrome X, CVD, diabetes etc. Family history of specific diseases reflects the consequences of genetic susceptibility, shared environment and common behaviors (Yoon et al., 2002). Family history has been recognized in clinical medicine as an important, yet non-modifiable, disease risk factor that when present could

* Corresponding Author's Email: mithundas01@yahoo.com.

influence the probability of a suspected diagnosis. However, collection and interpretation of family history has rarely been applied in the practice of preventive medicine to assess disease risk and influence early detection and prevention strategies (Scheuner et al., 1997; Williams et al., 2001). The advantages of family history over other genomic tools include a lower cost, greater acceptability, and a reflection of shared genetic and environmental factors. However, the utility of family history in public health has been poorly explored (Valdez et al., 2010). Professional guidelines usually include family history to assess health risk, initiate interventions, and motivate behavioral changes.

Family history of diabetes is not only a risk factor for the disease but is also positively associated with risk awareness and risk-reducing behaviors. It may provide a useful screening tool for detection and prevention of diabetes (Hariri et al., 2006). In a study among the adult Chinese, it was found that sufficient physical activity and negative family history of diabetes might jointly reduce the risk of developing hyperglycemia and T2DM (Xu et al., 2011). In the US population, family history of diabetes showed significant, independent, and graded association with the prevalence of diabetes. This association not only highlights the importance of shared genes and environment in diabetes but also opens the possibility of formally adding family history to public health strategies aimed at detecting and preventing the disease (Valdez et al., 2007). In another study on a nationally representative sample of US adults without diabetes, family history of diabetes showed a significant, independent association with syndrome X and its traits. This association supports the idea that shared genes and environment contribute to the expression of complex traits such as diabetes and syndrome X (Ghosh et al., 2010). Evidence suggests that family history by itself is most useful for predicting disease when there are multiple family members affected, the relationship among relatives is close, and disease is premature, that is, it occurs at younger ages than would be expected. It has been mentioned that family history information in combination with other known risk factors could be used to provide more personalized information about our risk for common diseases (Yoon et al., 2002). Moreover, it has been suggested that adding family history of diabetes could provide significant improvements in detecting undiagnosed diabetes (Yang et al., 2010). In another study, it was found that not only the adults, even the youths with a positive family history showed signs of increased risk for these conditions which indicates the importance of family history approach to screening for children at risk of diabetes and CVD (Valdez et al., 2007). In a study from India, it was found that individuals with positive family history of diabetes had significantly higher prevalence of syndrome X and its confounding factors as compared to their counterparts (Das et al., 2012).

It suggests that family history could be used as a tool for genomic studies among the Asian Indians as well as in other world populations. It is however reasonable to argue that in developing countries including India, a large section of the community remains undiagnosed and therefore accuracy of self-reported family history could be challenging. In addition to risk assessment, family history information can be used to personalize health messages, which are potentially more effective in promoting healthy lifestyles than standardized health messages (Janssens et al., 2012). Having a family history of a disease increases its salience and does not change one's perceived ability to prevent the disease (Acheson et al., 2010). To establish family history as a public health tool, it needs to be evaluated within the ACCE (analytical validity; clinical validity; clinical utility; and ethical, legal, and social issues) framework. These advances will help realize the potential of family history as a public health tool (Valdez

et al., 2010). It seems that population screening would be of substantial importance for further research as family history of chronic diseases plays a vital role in better understanding of the etiological factors related to such complex traits, and hence could be used as a tool for preventive strategies.

PHYSICAL INACTIVITY

The identification and modification of the root cause, overweight/obesity, physical inactivity, and the closely associated condition - syndrome X, needs to be one of the initial strategies that are addressed by the clinician (Borgman et al., 2006). Each component of syndrome X predisposes people to atherosclerosis, and when clustered together, these components promote atherosclerosis even more prominently. It has been found that lifestyle modification, such as physical activity level (PAL) and dietary habits reduces the risk of syndrome X (Yao et al., 2003; Katzmarzyk et al., Panagiotakos et al., 2004).

Studies have shown that sedentary lifestyle could predict the development of syndrome X. Both vigorous and moderate leisure-time activities were found to be beneficial to the metabolic syndrome cluster of cardiovascular risk factors among the adult men and women of U.K It was suggested that even modest increases in physical activity was worthwhile in public health targets (Rennie et al., 2003). In a study from India, it was found that individuals with low physical activity level (PAL) had much higher prevalence of MetS than individuals with moderate PAL. The lowest prevalence was observed among the individuals with high PAL (Das et al., 2012). It has been evidenced that Asian Indians who are physically active have a favorable metabolic profile which highlights the need to encourage physical activity in Asian Indian immigrants, particularly women, to reduce prevalence of MetS (Misra et al., 2005). Physical inactivity has also been found to be associated with the components of MetS and coronary artery disease (CAD) among the urban south Indian population. Lifestyle changes focusing on increasing physical activity supposed to prevent the exploding epidemic of MetS and CAD in India (Mohan et al., 2005).

The China National Nutrition and Health Survey (2002) reported that individuals who were active or very active were 40% less likely to have MetS compared with those who were leading sedentary life (Ma et al., 2008). Among the middle-aged and old Chinese adults, physically active individuals were found to have been associated with a better profile of inflammatory factors and adipocytokines and a reduced risk of having MetS (Zhijie et al., 2009). In a Finnish cohort study, baseline total leisure-time physical activity was found to be inversely associated with the risk of developing MetS during a 4-year follow-up (Laaksonen et al., 2002). In an another study among the adult men and women of Chinese Taipei, it was also found high amount of physical activity was inversely correlated with the left ventricular hypertrophy (LVH) and prevalence of MetS (Dao et al., 2009). Moderate and vigorous physical leisure-time activities were each associated with reduced risk of being classified with MetS independently of age, smoking, and high alcohol intake both among the U.S. men and women (Rennie et al., 2003). Total physical activity (measured as habitual energy expenditure) and fitness (measured as maximal oxygen consumption per kilogram) shown to have independent effects on the components of MetS (Wareham et al., 1998). It has been found that insulin action could be modulated by body weight and physical fitness which is a

core feature of MetS (Reaven 2001). It therefore seems that modulation of MetS is a plausible biological pathway through which physical inactivity may affect cardiovascular health.

To prevent increasing morbidity and mortality due to obesity-related diabetes and CVD in developing countries, there seems to be an urgent need to initiate large-scale community intervention programs focusing on increased physical activity and healthier food options (Misra & Khurana 2008). In the World Health Survey (2002–2003), data of 212,021 adults from 51 countries, most of which were from developing countries showed that about 15% of men and 20% of women were at risk for chronic diseases due to physical inactivity (Guthold et al., 2008). Among the Asian Indian immigrants living in U.S (Misra et al., 2005) as well as those living in Indian (Mohan et al., 2005) it was found that physical inactivity was highly associated with MetS phenotypes. Although at what intensity activity may be of benefit in reducing the risk of MetS is not yet clearly understood, but one thing is clear that active lifestyle could curb this epidemic of obesity related metabolic disorders.

DIETARY INTAKE OF FATTY ACIDS

Lack of habitual physical activity and certain dietary patterns, including high saturated fatty acids (SFA) and low vegetable intakes, contribute to weight gain and increase the risk of metabolic disturbances (Feskens et al., 1995). Saturated fat intake is associated with increased risk of coronary heart disease (CHD); the greatest risk reduction is associated with poly unsaturated fatty acids (PUFA) followed by mono unsaturated fatty acids (MUFA) (Kris-Etherton et al., 2001). In Asian Indians, there existed significant inverse association between central obesity measures and intake of unsaturated fatty acids due to recent shift in dietary habits causing an increase in the prevalence of obesity and dyslipidemia in this region. It was that intake of saturated fat may be a major risk factor for the onset of MetS in adult Asian Indians. Moreover, it appears that it is not the total fat but the amount of saturated fat consumed in association with TFA:SFA, SFA:MUFA, and SFA:PUFA was adversely affecting the adiposity level, lipids, blood pressures, and blood glucose levels in this population and in turn cumulatively enhancing the possibility to predispose to MetS phenotypes ((Ghosh 2006; Ghosh 2007; Das et al., 2010). The findings of an adverse impact of TFA:SFA intake and inverse relation of adiposity with PUFA, i.e., protection of polyunsaturated fat concerning the association with MetS is in accordance with the finding of several other investigations (Das et al., 2010).

Certain dietary patterns, including high SFA and low vegetable intake, contribute to weight gain and increase the risk of metabolic disturbances, whereas such potentially modifiable lifestyle factors may reduce cardiovascular risk (Feskens et al., 1995; van Dam et al., 2002). In a study from India revealed that increased dietary ω -6 PUFA and saturated fat intake are significantly associated with fasting hyperinsulinemia and subclinical inflammation, respectively, and found to be responsible for the increasing prevalence of insulin resistance, the MetS and diabetes (Feskens et al., 1995; Misra & Misra 2003; Misra & Khurana 2009; Ghosh 2009). In another study, it was found that the dietary total fat may increase whereas linoleic acid intake may reduce the risk of MetS in Japanese descendants living in Brazil (Cardoso et al., 2005). Study from the United Arab Emirates (UAE) pointed out that poor dietary habits including consumption of high-energy foodstuffs, diets high in total carbohydrates, fat, and

simple sugars were associated with MetS (Al-Sarraj et al., 2010). In a multiethnic study (comprising of African-Americans, Whites and Hispanics) on healthy children aged 7–12 years revealed that diet composition was more closely related to the components of the MetS than was physical activity, with carbohydrate intake being adversely related to WC, TG levels, and glucose levels. Moreover, relationships among diet and MetS outcomes were stronger among African-American children (Casazza et al., 2009) reflecting ethnic variation. It seems that while dealing with MetS in Asian Indians, or any world populations, researchers and clinicians should consider obesity measures, metabolic profiles and dietary fatty acids simultaneously. Since it is not the amount of calorie intake but the amount of fatty acids which seems to be associated with obesity related metabolic disorders.

EPIGENETIC MODIFICATIONS

The term epigenetics itself describes the concept as ‘epi’ means above and it was Conrad Waddington who, in 1940, provided the first broad and operational definition of epigenetics as “the causal interactions between genes and their products, which bring the phenotype into being” (Waddington 1940). Epigenetics has been defined as the study of heritable changes in gene expression that occur in the absence of a change in the DNA sequence itself. In mammals, these changes are mediated through DNA methylation, covalent histone modifications, microRNA, and poly-comb group complex recruitment (Dolinoy 2008; Schwartz & Pirrotta., 2008). The epigenetic marks either alone or in combination alter the chromatin structure and function, and thereby promote or inhibit gene transcription. Therefore, chromatin is the ideal substrate for nutrient-sensitive transcriptional instructions, existing in multiple permutations leading to multiple phenotypes. In addition, the epigenetic state of chromatin can undergo transgenerational epigenetic inheritance, a process facilitated by the incomplete erasure of epigenetic modifications during gametogenesis and embryogenesis, resulting in a maintained epigenetic state in future generations (Bruce & Hanson 2010).

Susceptibility to Syndrome X has an inherited or familial component. Although some fixed genomic variations have been associated with high risk but such single nucleotide polymorphisms attribute very little to the overall risk in the population (Gluckman et al., 2007). Whereas, subtle alterations in gene expression are responsible for an increased risk of disease outcome in many members of the population to a variable extent, rather than genomic alterations, such as those involved in placental nutrient transport. In recent years, epigenetic regulation leading to such subtle modulations in gene expression (without a change in DNA sequence) of key metabolic genes has emerged as a contributing factor to increased susceptibility to Syndrome X (Bruce & Hanson 2010).

Positive natural selection describes the increase in the prevalence of beneficial traits in a population, and is one of the factors driving evolution. A trait under positive selection must be beneficial, thus increasing survival and reproduction, and the trait must also be heritable. This positive selection has been attributed to particular DNA variants that become more common since of the beneficial effects on those who carry them (Kelley & Swanson 2008). However, a trait that may be advantageous at one point in human history may be detrimental under different environmental conditions. Here comes the classic example of *‘thrifty*

genotype,' a concept coined by the geneticist James Neel to explain the prevalence of obesity and diabetes (Neel 1962). Neel hypothesized that people with diabetes often have allelic variations in certain genes that enable them to efficiently collect and utilize food. The human variations which were favorable in populations facing challenges of episodic undernutrition might be disadvantageous when food supplies became abundant. It provides a possible explanation for why the propensity to diabetes varies greatly among populations. Carriers of these variations are, therefore, at a high risk of developing obesity and diabetes when exposed to abundant and cheap supply of energy, and a dramatic reduction in energy expenditure. This thrifty genotype would have been beneficial during periods of history characterized by food instability (Stoger 2008). In contrast to the long-term nature of the selective forces that are hypothesized to have positively selected the thrifty genotype, epigenetic changes occur rapidly to alter metabolism. There are ways in which epigenetic changes increase disease risk, perhaps in combination with evolutionarily mediated phenotypes.

Throughout history, humans have had to cope with adverse environmental changes such as periods of plague or famine. Famines provide an ideal setting to examine the biological adaptation and long-term consequences of unfavorable conditions, especially during human development. One of the most well documented events is the Dutch Hunger during the winter of 1944–1945. It was suggested that epigenetic mechanisms underlie the increased incidence of Syndrome X in adults prenatally exposed to the Dutch famine and the transgenerational effects of prenatal exposure to the Dutch famine in the grandchildren of women exposed (Painter et al., 2008). A sex-specific increased risk of obesity, dyslipidemia, and cerebrocardiovascular-related deaths has been observed six decades later among those whose mothers were exposed to famine early in gestation (Kyle & Pichard 2006). The outcomes of these studies strongly support that *in utero* exposure to famine may result in adverse metabolic phenotypes, which depend on the sex of the exposed individual, and the timing of exposure during gestation as the embryo is more vulnerable around the time of conception. Similar observations inspired the Barker's hypothesis almost three decades ago, also known as the '*thrifty phenotype*' that malnutrition acts not as a selection acting over many generations to alter the genetic make-up of the population, rather the early environmental (including prenatal environment) influence acting in an individual to increase the susceptibility of the disease (Hales & Barker 2003) .

In Neel's hypothesis, entire populations have an increased predisposition to diabetes due to genetic selection. They are better adapted to different nutritional circumstances than those they experience today. In Baker's hypothesis, maladaptive responses occur as a result of environmentally induced alteration of physiology in the early life of the individual. Both hypotheses offer explanations of why the frequency of diabetes and obesity differ in different populations. People in the Indian subcontinent, for example, have faced undernutrition for many generations, and Indian babies (new born) are among the smallest in the world (Yajnik 2003). However, diabetes epidemic is of recent origin, and it is more common among urban than rural Indians despite the higher birth weight of urban babies. The two explanations (hypotheses) are therefore not necessarily exclusive and may complement each other. Then there is a third hypothesis called the '*common soil*' hypothesis as proposed by Lebovitz (2006) that diabetes and CVD might share underlying cause(s) – hence termed common soil. It was mentioned that insulin resistance is central to the progression from normal glucose tolerance to diabetes and to a constellation of CVD risk factors known as Syndrome X.

Changes in adipose tissue and metabolism (perhaps mediated through epigenetic changes) might link insulin resistance and visceral obesity – a condition that is common in diabetes.

Epigenetics may provide a mechanism by which developmental plasticity mediates developmental priming. Therefore, epigenetics may be the interface between nutritional stimuli during development and resulting phenotype, thus being central to the developmental origins of the Syndrome X (Bruce & Hanson 2010). The genomic information is the same in all our cells and during our entire lifespan, whereas, the epigenomic information varies from cell to cell and during the lifetime of the individual. An increased understanding of epigenetic mechanisms may lead to the development of novel and targeted therapies that will act not only at the risk-factor level, but also directly on the vascular system (Ordovas & Smith 2010). This makes epigenomic information more important for pharmacological interventions. In a recent epigenome wide association study (EWAS) it was found that methylation in *CPT1A* was significantly associated with syndrome X and it's confounding factors in both European and African ancestry participants. It indicated a promising epigenetic marker for metabolic disorder which could become useful for treatment target (Das et al., 2016).

Several compounds have been identified that are able to regulate DNA methyl transferase or histone deacetylase activity. DNA methylation is not just the driving force behind the developmental priming of disease but also a channel that transfers information of the transcriptional patterns required in a particular environment. Epigenetic modifications facilitate a transcriptional state, which may be inherited and may impart an increased risk of Syndrome X development in the context of unfavourable environmental conditions. Therefore, it is not the epigenetic landscape that is ultimately causal to the phenotype but the stimulus that it receives at the cellular level. This in part explains tissue-specific epigenetic modulations, because each particular tissue will receive specific stimuli and resides within a unique milieu (Bruce & Hanson 2010). Epigenetic control of key genes is central to the developmental priming of the metabolic syndrome (Syndrome X) phenotype, and provides a likely target for pharmacological therapies in near future.

ABSTRACT

Break the Cycle of Children's Environmental Health Disparities (*Break the cycle*) is an annual collaborative interdisciplinary research and training program involving university students in academic tracks that focus on the impact of adverse social, economic and environmental factors on children's health, development, and education. The target populations are communities where environmental hazards are related to circumstances of social and economic disadvantage. Each student develops a project that focuses on preventing or reducing adverse environmental factors to benefit the children who live in these communities. At the end of the project, the students present their studies and findings at a national conference, and write papers which are then published in a journal issue. The projects cover a range of factors that operate over the lifespan, and have an influence on individual, community, and social perspectives. Most importantly, they inform us about children's environmental health disparities, and propose solutions to reduce and eliminate health disparities and promote health equity for all children.

INTRODUCTION

The papers in this book represent the work of students who participated in the 12th Annual *Break the Cycle* program. The phrase *Break the Cycle* in this context uses the ecological construct of a cycle of environmental health disparities (Figure 1) and represents a strategy for reducing health disparities and promoting health equity among children who are vulnerable as a consequence of adverse social, economic environmental factors, thereby 'breaking the cycle'.

Children who grow up in poverty are often exposed to poor indoor air quality, which increases the risk for asthma and respiratory disorders, and to high lead levels from old paint which can result in brain damage. In addition, they are at risk for a variety of other environmental exposures, stresses, and abuses including food insecurity, housing insecurity, and fear of physical injury, with real experiences of neglect and abuse which, cumulatively, can result in the physiological phenomenon of chronically elevated cortisol levels and "toxic stress" which is associated with adverse structural and functional changes in the brain with life-long implications that can result in reduction in brain volume in white matter, in grey

matter, and specifically in the hippocampus and amygdala [1]. As they reach adolescence, these children are more likely to engage in risky behaviors, including unprotected sexual activity that can result in teenage pregnancies or sexually transmitted diseases, substance abuse, school failure, gang membership, and crimes which can result in incarceration or death from drugs or gun violence. The elevated cortisol levels associated with toxic stress also affect the cardiovascular, immune and hormonal systems, and, as adults, they are more likely to have adverse health outcomes such as obesity, diabetes, and hypertension, with associated morbidity and mortality [2].

Figure 1. Cycle of environmental health disparities [3].

The physical, chemical, biological, and social environments that children experience before birth, early in life and through adolescence may have life-long consequences that also affect subsequent generations. There is ample evidence that children who grow up in poverty and experience adverse social and environmental factors will have more health problems, neurodevelopmental disorders, learning disabilities, attention difficulties, and school failure. These children have relatively poor educational opportunities and limited access to quality healthcare services, which contribute to the social determinants of adverse health and developmental outcomes [3]. The unfavorable health, developmental, and educational outcomes compromise the child's opportunity for economic and social success and often result in an intergenerational cycle. It is the codification of this construct that embodies the concept of the cycle of children's environmental health disparities. Figure 1 captures the

interrelationship between economic, social and environmental factors, and the health outcomes of children, as well as the intergenerational trajectory that serves to perpetuate the cycle.

BREAK THE CYCLE PROGRAM

“Break the Cycle of Children’s Environmental Health Disparities” (*Break the cycle*) is an annual collaborative interdisciplinary research and training program involving university students in academic tracks that focus on the impact of adverse social, economic, and environmental factors that affect children’s health, development, and education. The target populations are communities where environmental hazards are related to circumstances of social and economic disadvantage. Each student develops a project that focuses on preventing or reducing environment related disorders for children who live in these communities. At the conclusion of the project, the students present their studies and their findings at a national conference and write papers which are then published in a journal supplement devoted to the collection of projects from each given year [3].

Proposals are submitted by students to a competitive review process that evaluates the quality of the proposal, relevance to children’s environmental health disparities, creativity, and feasibility. The selected students will work with their academic mentors and with the *Break the cycle* faculty. The students and their mentors participate in monthly conference calls, during which the progress of each project is reviewed, additional perspectives are explored, and constructive guidance is provided. During these conference calls, the students and their mentors have an opportunity to communicate and collaborate with their counterparts at other universities.

Since the inception of the Break the cycle program in 2004-2005, we have had 11 annual programs and worked with over 100 students representing 30 different university departments in 10 states in the United States (US), as well as students from countries in Latin America, Europe, and Africa. To date, we have had nine monographs published in international journals and nine books in a public health series. In 2012, we completed a survey of past students who rated their experience with *Break the cycle* valuable, and many reported that they pursued careers relating to their *Break the cycle* projects [4].

We started the program with the expectation was that the projects would make a difference in improving the health and well-being of the children, their families, and their communities. We also envisioned that the students would be inspired to pursue careers that focused on reducing health disparities and in becoming our future leaders. Furthermore, because each student has a mentor at their home university, we were hopeful that the faculty mentors would add elements of the concept and literature on the subject into their curricula, and thereby promote further research and academic interest in this field (see Table 1).

We also expected that the participating students would inspire others in their academic, social and professional circles, and that the interdisciplinary nature of the program with participation of students at other universities around the world would be stimulating and inspiring (see Table 2). The 2012 survey also showed that the students derived significant benefit from all aspects of their participation in the process, which included the practical aspects of conducting a research project, experience in preparing and delivering a

presentation and writing a manuscript. Each student gained knowledge about children's environmental health and environmental health disparities, and was exposed to different perspectives from the other student projects. Many participants reported that their participation in the program influenced their career choice [4].

Table 1. Project guidelines

- University faculty identify students who have an interest in this topic area, and encourage and support the student in the selection of an idea for research, specifically looking at projects that address environmental factors that adversely affect the health of children living in circumstances of social and economic disadvantage. Alternatively, students interested in a specific project can identify mentors to work with them.
- The students submit a proposal which is subject to review by the *Break the cycle* faculty. The process is competitive with approximately 10 projects being selected each year.
- During the project period, there are monthly conference calls with all students and mentors to monitor the progress of the research projects, share ideas, and assure that the project is consistent with the spirit of the *Break the cycle* concept.
- At the end of the project period, the students present their projects at a conference with a keynote speaker of national stature.
- The students write papers on their projects, which are submitted for publication in an international journal as a monograph of the *Break the cycle* projects. The papers are also published as chapters in a book.
- Funding of travel expenses within the United States and accommodation for the conference are provided for the student and faculty mentor. A modest stipend is provided to the students once they have completed the project and submitted their paper.
- The progress and careers of the participating students are tracked to evaluate the impact of their participation in the *Break the cycle* program.

Table 2. Desired outcome

- To inspire students from a variety of academic disciplines to explore the relationship between adverse social, economic and environmental factors and the health, development and education of children and to creatively generate strategies to address the challenges
- To collaborate with an interdisciplinary team of academic leaders from different universities and colleges to creatively examine the broader issues of this topic area
- To encourage faculty at universities who participate in this program to promote academic interest and social awareness in children's environmental health particularly in children's environmental health disparities
- To cultivate future leaders

BREAK THE CYCLE 12 PROJECTS

We are pleased again to have a wonderful interdisciplinary array of creative projects developed by students in six states in the US and one from Zambia. The papers in this volume cover the lifespan from consideration of prenatal vulnerabilities of the fetus, to the outcomes

of premature newborn infants through personal, family, community and social perspectives. They look at health, nutrition, education, environmental exposures, legal aid, incarceration, education of children and community engagement. Of note is that they cover the full cycle of children's environmental health disparities and provide solutions to reduce and eliminate these disparities. The following are brief reviews of the *Break the cycle* 12 student projects:

Prenatal Exposures and Their Consequences

We have been aware of concerns around the adverse effects of prenatal exposures on the developing fetus for decades. Our first shocked realization came in the late 1950s, when we recognized that infants born to mothers who had taken the drug thalidomide had limb reduction anomalies directly attributable to the drug [5]. The drug was immediately withdrawn from the market, the field of teratology gained credence and, since then, we have become aware of the risks to the developing fetus of maternal ingestion of medications. In the 1960's, we recognized that infections during pregnancy such as rubella could result in significant harm to the developing fetus [6]. We now recognize that vaccines administered prior to and during pregnancy prevent intrauterine infections and result in improved outcomes for mothers and babies [7]. In the 1970s, we learned that alcohol consumption during pregnancy can result in serious physical and neurological effects and abnormal fetal development and infant behavior [8]. We have become increasingly aware that infectious agents, chemicals, and maternal behaviors such as smoking and taking drugs can adversely affect the fetus [9].

In the paper by Pratibha Agarwal, MD, a pediatric resident at the East Tennessee State University in Johnson City, Tennessee, we get a glimpse into the current national epidemic of opioid abuse. Opioid addiction has led to a startling increase in drug related deaths in the USA. When pregnant women abuse opioids, it leads to the clinical phenomenon of Neonatal Abstinence Syndrome (NAS) [10]. Tennessee and Kentucky have higher death rates from overdose of opioid painkillers, combined with other drugs such as heroin, than other states and both have seen an increase in the death rate from 2014-2015 [11]. The involved population tends to be Caucasian rather than African-American. This phenomenon is related to education, employment, changing socioeconomic status, and disparities in access to health care. In this study, the babies with neonatal abstinence syndrome were predominantly children of mothers who were poor, had limited education, had unstable family relationships, and had used multiple substances.

As of this writing, steps have been taken to reduce the risk of addiction by raising awareness nationally particularly among prescribing physicians, limiting the number of tablets that can be prescribed, and developing rehabilitation programs based on the Alcoholics Anonymous (AA) model. It is also interesting to note that many individuals who are addicted to opioids end up incarcerated and become the mothers who are described in the paper by Tatenda Mangurenje in this volume. It is also of note that the US has the highest rate of incarceration in the world and some of the reason (as stated in the referenced paper) relates to its policy on drugs. In contrast to the US, other countries view substance abuse as an illness that requires treatment, and have a lower rate of substance abuse, lower rates of mortality from drugs, and much lower incarceration rates.

Promoting Breastfeeding among Adolescent Mothers

For educated mothers, the benefits of breastfeeding may appear obvious. Breast milk is readily available, provides incalculable nutrients with immune properties, and has been the sole sources of nutrition for infants since the dawn of mammalian evolution. Breastfeeding is convenient, inexpensive, and it promotes mother infant bonding. What happened to change breastfeeding practices? Historically [12], high maternal mortality rates threatened the survival of the infant as there would be no source of nutrition, and, unless a substitute 'wet nurse' could be found, the infant would be at risk for dying of malnutrition. The use of milk from domestic animals provided that life-saving intervention. Initially, improvised modes of dispensing the milk were used, but as technology advanced, glass bottles with modified 'nipples' were developed. As our technology advanced, a milk substitute was developed, and bottles and artificial nipples were produced. The marketing of this form of infant feeding resulted in a dramatic drop in breast feeding and almost total reliance on artificial formula feeds. While this was a regrettable trend among high resource locales, it was devastating in low resource areas as it significantly contributed to illness and high infant mortality from malnutrition and diarrheal diseases.

In low resource areas of the world, water is added to a milk powder to provide liquid formula. Poor sanitation and the use of contaminated water for the formula is likely to result in diarrheal disease. Low income mothers tend to use more water than recommended to stretch their supply of milk powder, which results in malnutrition and susceptibility to infections such as pneumonia, tuberculosis and diarrheal illnesses; all of which can be fatal in malnourished infants. The United Nations Children's Fund (UNICEF) reports that breastfed children have at least six times greater chance of survival in the early months than non-breastfed children, and that an exclusively breastfed child is 14 times less likely to die in the first six months than a non-breastfed child. Despite this, it is estimated that only 39 percent of children less than six months of age in the developing world are exclusively breastfed [13]. There is still much work to do to promote breastfeeding, and thereby reduce infant mortality in low resource countries, as well as in countries where there is high income disparity and consequently high disparities in children's health. The paper by Colleen Clark, a student, in the Public Health Program, Center for Graduate Studies at Lenoir-Rhyne University, in Asheville, North Carolina, looks at helping to promote breast feeding among low income adolescent mothers and thereby break the cycle for their children and future generations – a worthy project with substantial benefits and need for expansion and replication.

Coordination of Care for Premature Infants and Their Families

Since the 1970s, when technology was harnessed to improve the survival of premature infants, we have witnessed a dramatic increase in the survival rate of extremely premature infants. We now see survival of infants born at 23-24 weeks gestation weighing a little over 500 grams or 1 pound. Premature infants may spend 3-5 months in the neonatal intensive care unit (NICU), where the costs in the US now average \$3,000 a day; the average cost of NICU care of a premature infant is \$40,000. With increasing prematurity, there is an increasing likelihood of long term neurological and medical complications, which come with their own

long-term costs. But costs in dollars are only part of the picture; the emotional, psychological, social and economic burdens that families of premature infants face are complex and daunting.

Although the over-all rate of prematurity is 1 in 10 pregnancies, poor African American women have a much higher rate than Caucasian women – 13% vs 9% [14]. Many of these premature infants are born into poorer African American families, with limited access to quality healthcare, early intervention services, good education, or legal assistance. These factors make the long-term outcome for the children much less promising, perpetuating the cycle of health disparities.

In the paper by Lea Redd, a student in the Department of Pediatrics and Neonatology, at the University of Chicago Medical Center, in Chicago, Illinois, the mobilization and utilization of the Health Law Partnerships to assist low income-low resource families in their practical struggles was demonstrated to be of significant benefit in breaking that cycle. This increased access led to improved developmental outcomes for the infants and less stress for the mothers. There are many Medical Legal Partnerships across the country, and the recommendation is that every NICU should have such a program in place to enhance services for the vulnerable infants and their families [15].

Impact of Early Life Housing on Child Behavior at Age Seven

Children who are born into circumstances of social and economic disadvantage tend to suffer additional adverse life experiences that can affect their physical and mental health and well-being during childhood, adolescence and adult life. Adverse childhood experiences [16], such as death of a family member, a move, and illness or natural disaster, do not necessarily result in long term adverse consequences if there is a supportive and nurturing family member to help with the reestablishment of a regular life routine, indeed, the children recover and may even be strengthened by their experiences. However, repeated and relentless emotional and physical assaults without the buffer of a supportive and nurturing family member can have serious lifelong negative impacts on the child's health. These adverse experiences may come in the form of neglect, with emotional, physical, or sexual abuse, with fear of abuse, and with insecurity of different types including food insecurity, financial insecurity, and/or living/housing insecurity. These children suffer from chronically elevated stress hormones in the form of cortisol which, in the long term, has a damaging effect on the hormone system, the immune system, and brain metabolism and brain architecture. This state has been termed 'toxic stress', and is associated with physical and mental disorders in childhood, adolescence and adulthood, with a reduced life expectancy from drugs and gun violence in young adulthood, to chronic cardiovascular, pulmonary, metabolic and immune disorders in older adults [17].

In her project on housing and child behavior, Abby Gaylord, from the Department of Environmental Health Sciences, Mailman School of Public Health, Columbia University, New York City, explores the impact of housing insecurity on the development and behavior of children at age seven years. She notes that there is a serious pattern among low income families who cannot afford stable housing and must settle for less than optimal rental homes. These homes are likely to be old, with poor heating and ventilation systems and increased risk

of lead exposure due to deteriorated old paint. These homes are often situated in older decaying neighborhoods, with air, water and soil pollution, increased exposure to a drug culture, and crime and poor quality schools. Families face the monthly struggle of paying rent to avoid eviction and the inconvenience and expense of moving to a home of comparable quality. In his book entitled "Eviction," Matthew Desmond paints the picture of poor families in Milwaukee who struggle to find and stay in safe and secure homes. Unreliable employment and unforeseen expenses lead to frequent difficulties in paying rent, which leads to evictions by landlords trying to maintain properties and make a profit [18].

In her study, Abby Gaylord found that children who experienced multiple moves were more likely to have adverse developmental and behavioral consequences. She also found that material hardships were strongly associated with an increased likelihood of moves, and explored strategies to reduce socioeconomic strain, which, she postulates, will have the greatest impact on breaking the cycle in reducing children's health disparities related to housing instability.

Home, Belonging and the Incarcerated Mother: A Study on the Effects of Mass Incarceration on Children's Behavioral Health Outcomes

The original conceptualization of the "Cycle of environmental health disparities" was focused more on the social and economic elements with poverty at its core and hence poor education and poor health care services (see Figure 2) [19]. At the time, we characterized the cycle as involving children growing up in poverty with limited education and employment opportunities, and a dim view of the future which lead to disillusionment and despair. As a consequence of limited mental health care services, the adolescents would turn to tobacco, alcohol and other drugs to self-medicate. Young women with no access to contraception would get pregnant, receive little prenatal care, abuse illicit drugs, and often deliver premature infants. These children would grow up at a neurological disadvantage from birth and then enter into unstable homes with the possibilities of neglect and abuse. Thus the cycle would be repeated. What we had not written into our narrative at the time were the results of substance abuse and its behavioral consequences, and the lack of employment and income, leading to the need for getting money by less than socially acceptable means such as stealing or prostitution. The next step in this process is not difficult to see – arrest and incarceration. Although this is the likely mechanism for incarceration for many, the harsh laws that were enacted in the 1990's have resulted in an explosion in the prison population that puts the US at the top of the list of countries in the world, with a per capita incarceration rate of greater than 700 per 100,000 of the population! In Russia the rate is 581 and at 145 in Britain which is at about the midpoint worldwide [20].

This prison population not only costs the US taxpayer approximately \$50,000 per year per person in prison, but the real cost to families and society is far greater because it perpetuates the dissolution of the family as well as the community and society, robbing children of opportunities to have parents in their lives and of society to have active participating and contributing members of society to build and stabilize society.

Tatenda Mangunje, a student in the Department of Anthropology and Global Health at Emory University in Atlanta, Georgia, studied a population of women in prison and looked at

the impact on the children's development and behavior. Needless to say, she found that the children whose mothers were in prison suffered significantly, not only in the present, but for their futures. She challenges us to look at ways of protecting the children, whose mothers are incarcerated, to help them to survive the difficult times and thereby have more chance of success in life. The greater challenge is to our society, to change the harsh and unfair practices and help to assure that future generations of adolescents and parents-to-be have opportunities to have a good education and the hope of gainful and meaningful employment. That would be a good outcome.

Figure 2. The original conceptualization of the “Cycle of environmental health disparities.”

Neurodevelopmental Outcomes of Recent Exposure to DDT in Children of Selected Communities of Zambia

DDT (dichloro-diphenyl-trichloroethane) was developed as the first of the modern synthetic insecticides in the 1940s [21]. It was initially used with great effect to combat malaria, typhus, and the other insect-borne human diseases among both military and civilian populations. It also was effective for insect control in crop and livestock production, institutions, homes, and gardens. The problem, however, arose with its widespread and indiscriminate use being sprayed from trucks and from airplanes over vast areas, resulting in extensive exposures and bioaccumulation with a set of unanticipated consequences. Because it is one of the fat soluble persistent organic compounds, it bio-accumulates in fatty tissues, particularly the brain, and can result in a variety of neurological effects in humans as well as in animals. It can also affect the liver, kidneys, and immune system. Because DDT enters the

bodies of the insects, and birds eat the dying insects, the toxin bioaccumulates in the birds and can cause brain damage. In addition, it interferes with calcium metabolism, resulting in weak egg shells which then results in the breaking of the shells when the birds sit on the eggs to incubate them. This phenomenon, along with the acute brain and liver toxicity associated with high doses of the DDT, resulted in a dramatic drop in certain bird species, with local extinctions in some areas. This threat to birds was the centerpiece of the 1962 book “Silent Spring” by Rachel Carson [22] that resulted in sufficient scrutiny on DDT to lead to the banning of DDT in the USA and then subsequently in other parts of the world. It was also a factor in the formation of the US Environmental Protection Agency (EPA).

In reality, Carson did not advocate that DDT should be totally banned; she recommended measured and judicious use, citing concerns around toxicity to humans and animals, concern around upsetting the ecosystem and possibly resulting in the proliferation of other pests, and the concern around the development of resistance among the insects, particularly the mosquito. The use of DDT had effectively eradicated malaria from some parts of the world, which remains a scourge and cause of death for much of the developing world. In Africa, malaria is the fourth leading cause of death after HIV/AIDS, respiratory infections, and diarrhea. It therefore is critically important to reduce or eliminate the malaria mosquito; it is in this context that careful and judicious use of DDT could be warranted. In her paper, Nosiku Munyinda, from the Department of Public Health at the University of Zambia in Lusaka, Zambia, examined the possible adverse neurodevelopmental consequences on children of the use of DDT in preventing malaria in a poor area of Lusaka. Interestingly, she did not find a correlation with DDT levels and neurodevelopmental problems. On the contrary, she found that psychological, social, and economic factors played a larger role in adverse developmental outcomes. It may be that the DDT levels were not sufficient to affect the central nervous system (CNS) or that positive psychological and social factors could mitigate the adverse effects of the DDT. As always in medical management, the risks and benefits need to be thoughtfully weighed to determine the best possible approach to management. But ultimately, wherever there is poverty, there is more likely to be an adverse effect on a child's development. We know that early intervention can make a difference even for the poorest and most involved infants and children in the poorest countries [23], so early intervention should be provided for all infants in low resource communities.

Racial Disparities in Access to Municipal Water Supplies in the American South: Impacts on Children's Health

In high resource countries, we take clean water for granted; we turn on our taps and there is clean water that we can drink – we assume safety. But this is not the case for many parts of the world with limited resources. The World Health Organization (WHO) reports that 884 million people lack even a basic drinking-water service; including 159 million people who are dependent on surface water, and more than double that number use water that is potentially contaminated, resulting in an estimated 500,000 deaths from diarrheal illnesses a year – most of those are children [24]. The Sustainable Development Goal #6 is to *ensure availability and sustainable management of water and sanitation for all* so there is a significant challenge ahead [25]. In our 10th Annual Break the Cycle program, Chalwe Chanda, a student at the

University of Zambia, looked at environmental risk factors in children living in a poor area on Lusaka, Zambia and found a significant association between the combined factors of water supply and sanitation with malnutrition in the children [26]. We do know that diarrheal illness in a malnourished child is associated with a high mortality.

This year, Frank Stillo, a student in the Gillings School of Global Public Health, at the University of North Carolina in Chapel Hill, looked at an African American community in North Carolina, where the water source was from unregulated private wells rather than from municipal sources, and reflects health disparities attributed to social and economic factors. Frank and his mentor, Jackie McDonald Gibson had already reported on the presence of microbial contaminants in this water source [27], and, in this study, they looked at the presence of lead contamination. The presence of lead in drinking water is of serious concern for children whose developing brains are acutely sensitive to lead, which can result in significant functional impairment. This reality was highlighted in the recent finding of contamination in the Flint, Michigan water supply [28].

The lesson from these studies is that we need to be constantly vigilant about our water supply, whether it is the water supply for low resource regions of the world or for low income minority or marginalized populations in high resource counties.

Interactive Educational Lead Hazards Class to Children at the Boys and Girls Club in Metro Atlanta

Lead is the most common heavy metal neurotoxin in our environment. Human history has a trail of lead and lead toxicity for thousands of years. In the mid-20th century, lead was present in significant quantities in gasoline and paint, and was the primary source of lead poisoning for children sometimes resulting in severe and permanent brain damage. During that time, clinicians were concerned with lead levels higher than 60 micrograms per deciliter ($\mu\text{g}/\text{dL}$). These levels resulted in severe encephalopathy and were an indication for chelation. Thanks to the indefatigable advocacy of Dr Herbert Needleman (1927-2017) for prevention of lead poisoning in children by removing lead from gasoline and paints [29], we have seen a substantial decline in the blood lead levels of children, and the recognition of developmental and behavioral consequences of lead levels below 5 $\mu\text{g}/\text{dL}$ [30]. The problem is that lead persists in our environment, mainly in older houses that still contain lead paint. It also persists in soil and in water, such as in the water supply in Flint, Michigan [28] and, as noted in the paper by Stillo in this volume, in other unexpected sources of water. There is also lead in some pottery, glassware, toys and folk remedies from other countries. In fact, internationally there have been major epidemics of lead poisoning, as an example from illegal mining in Nigeria using children for labor. That particular epidemic resulted in substantial long term neuroglial consequences for the children as well as a significant number of deaths [31].

The good news is that today we are aware of the harm to children's brains from even low levels of lead. As a result of legislation banning lead from paint and gasoline and actions taken by local, state and federal agencies, blood lead levels in children have fallen dramatically. We screen for blood lead levels above 5 $\mu\text{g}/\text{dL}$, because we know it can have a significant adverse effect on brain function. This is why we need to continue to be so vigilant. In their project on educating children about the risks and prevention of lead poisoning,

Catherine Evans, Amrita Mahtani, Sam Peters, and Patrick Fueta, students in the Department of Environmental Health, Rollins School of Public Health, at Emory University, in Atlanta, Georgia, developed a lead education program that they piloted at the Samuel L Jones Boys and Girls Club in Decatur, Georgia. This program “works to save and change the lives of children and teens, especially those who need us most, by providing a safe, positive, and engaging environment and programs that prepare and inspire them for healthy living and academic success to achieve ‘great futures’.” The Emory team found the children in the program to be very receptive, and their project was such a success that the US EPA plans to use their curriculum.

Educating children about toxins in their environment, as well as how to recognize it and what to do about it, is an invaluable way to promote children's environmental health and prevent exposure to lead and its serious consequences. This type of education will help provide children with the knowledge to influence their peers, their parents and the next generation.

The Effectiveness of a Community-Based Program of Nutrition Education and Physical Activity to Decrease Health Disparities of Childhood Obesity

Childhood obesity is a major challenge for families, their communities, and our society. Not only are children at risk for social, emotional and educational difficulties, but also for health complications with diabetes and hypertension that persist into adulthood and worsen physical and mental health, employment opportunities, and longevity. This presents a major cost, not only to the individual and his or her family, but also to society in terms of health care costs and productivity. This is particularly a challenge among low income African American children who suffer from food insecurity and tend to consume high calorie, high salt, and processed foods. They often live in so-called “food deserts,” with limited access to healthy fresh fruits and vegetables. These neighborhoods often lack green space for outdoor activities and exercise; consequently, the children are more likely to stay indoors and engage in sedentary activities, such as watching television (TV) or playing videogames. The combination of high calorie foods, low physical activity level, and stress is a toxic combination for the genesis of obesity.

To address this challenge, Hope Bentley, a student in the Department of Nursing and Allied Health, in the College of Veterinary Medicine, at Tuskegee University, in Tuskegee, Alabama, developed a program to address those very issues. She recruited economically disadvantaged youth from the Tuskegee Youth Safe Haven, which is an after-school program for youth 6-18 years old. She provided them with education in healthy eating and with an organized physical activity program. The good news is that, even for the relatively small size of her project and small number of children involved, she saw a significant benefit. This project, like so many others in the *Break the cycle* program, is small in scale but large in impact.

CONCLUSION

This publication of our 12th Annual *Break the Cycle* program reflects a diversity of projects and perspectives on the expressions of environmental health disparities in our societies and provides strategies that break the cycle. It is gratifying to see that the efforts of each student make a positive difference in our understanding of the health and wellbeing of children most impacted by adverse social, economic, and environmental factors.

We feel humbled by the magnitude of the challenges presented in the WHO Sustainable Development Goals (SDG) 2030 [25], particularly as our global community is dealing with causes and consequences of war, famine and disease, as well as the unpredictable hardships resulting from the impacts of climate change. The frequency of weather related disasters is increasingly considered to be responsible for the displacement of people from drought and famine in parts of Africa, and may have played a role in starting the war in Syria [32] with its devastating destruction of property, disruption of society and displacement of people. Such events result in political destabilization in the region, the loss of lives and livelihood, and a global refugee crisis. The planet is one global village, and environmental and political changes that take place at any particular place tend to affect everyone. However, just as we are affected by the negative events, we are heartened by the efforts that have been made around the world by large and small organizations, including the United Nations, the Bill and Melinda Gates Foundation [33], and not insignificantly, the students from the “Break the cycle” program. As long as the positive efforts continue, we have a good chance of achieving the Goals of SDG 2030, and having a future of health and wellbeing for all life on the planet.

Chapter 257

RESILIENCE: A COMMENTARY ON BREAKING THE CYCLE

I. Leslie Rubin*, MD

Department of Pediatrics, Morehouse School of Medicine, Southeast Pediatric
Environmental Health Specialty Unit, Emory University, Break the Cycle
of Health Disparities, Inc. and Developmental Pediatrics Specialists,
Atlanta, Georgia, USA

ABSTRACT

Resilience can be defined as achieving a positive outcome in the face of adversity. Resilience relies on the protective response of an organism from threats to survival. Human physiology has built-in mechanisms for dealing with all manner of threats with an immediate ‘fight, fright or flight’ response, followed by a more complex set of physiological, psychological and behavioral responses for sustained threats. This commentary offers an exploration of the phenomenon of resilience and will examine the physiological, psychological and social mechanisms that assure not only survival, but success as well. Perspectives on the anthropology, genetics, physiology, neurology, psychology and sociology of adverse childhood experiences will be explored, and strategies for enhancing the ability of children and adults to overcome the threats of negative psychological, social, economic and environmental factors will be offered. Personal narratives of individuals who had adverse childhood experiences and were able to rise above them and become successful are presented as examples of resilience.

INTRODUCTION

This commentary is the product of a symposium held during the “12th Annual Break the Cycle of Environmental Health Disparities Conference” in Atlanta, Georgia, in April 2017. In it, the author attempts to capture some of the current concepts of resilience as they may apply

* Corresponding Author’s Email: lrubi01@emory.edu.

to vulnerable children born into poverty and adverse experiences. It also offers insights on how to apply our understanding of resilience to provide enhanced support for these vulnerable children and promote their resilience to help them break free of the cycle to become self-respecting, respectable, and contributing members of society.

It is not the strongest of the species that survives, nor the most intelligent that survives. It is the one that is the most adaptable to change. Charles Darwin (1809-1882)

Figure 1. Cycle of environmental health disparities [1].

The conceptualization of the impact of adverse social, economic, and environmental factors on the health, growth and development of children offered here is based on the ecological framework of the “Cycle of Environmental Health Disparities” (see Figure 1) [1]. The cycle presupposes an intergenerational legacy of adverse experiences associated with poverty, in the context of cultural and political factors. For children who are born and grow up in this ecosystem, there are substantial risks for repeating the pattern [2]. For an individual to break out of this cycle, the challenge is to become aware of and examine the predicament, conjure up a vision of the future, generate and fire up the determination to make the necessary changes, and amass necessary internal resources to not only break out of the cycle and gain measures of self-respect, but also to take advantage of available opportunities to attain personal and social success. This process can be viewed as resilience. Resilience is defined as achieving a positive outcome in the face of adversity. However, it is more than overcoming adverse factors, it includes the quintessentially human phenomenon of rising above the experiences, adapting to a new set of circumstances, and of achieving success with a positive impact on the society at large.

BIOLOGY AND ANTHROPOLOGY OF ADAPTATION AND RESILIENCE

All life forms have mechanisms and systems of adaptation to adverse environmental factors that threaten their survival. Simple bacteria have survived almost since the origin of life on this planet because of their ability to adapt to environmental changes and threats to their survival. Some pathologic bacteria have developed resistance to many antibiotics, even some of the more potent ones.

More complex animals and plants each have their unique ecological niches that require a finite range of environmental elements to be compatible with life. These elements include ambient temperature, weather patterns, availability of water and nourishment, with effective strategies to deal with predators or competition, and some measure of climate change, that enable them to survive. When animals and plants experience threats to their existence, their genetically determined processes of adaptation are critical to resilience in overcoming the threat and continuing to survive.

For humans, interestingly, the ability to adapt to different and changing environments is so great that the species is able to live in the most varied and often inhospitable environments. Humans can live in and adapt to extreme temperatures, some live in hot dry deserts, while some live in frozen and icy environs, such as the Arctic Circle; some live in large crowded cities and some live in rural areas or on small islands in small communities.

In trying to explore and understand the realities and challenges of how humans survive in our modern communities, it is helpful to reflect on how our remote primal ancestors lived and survived in their environments when faced with the threats of harsh climates, predatory animals and real competition for food with minimal resources but their creative intellect. In his research on the hunter-gatherers of Southern Africa, primarily the !Kung San from Northwest Botswana, the anthropologist, Melvin Konner described the challenges to individual, family and community life [3]. These groups of people, who live in a harsh and arid climate, have survived for millennia, having adapted to their environment and circumstances. Day to day struggles and stresses of finding food and water in harsh surroundings challenge the physiological and psychological resources and resilience of this nomadic population. The necessity to find water, hunt for food, and deal with the real threats posed by predators, activates the physiological mechanisms of adaptation and resilience, which translates into psychological awareness, with corresponding physical and social action. There are also internal threats within the community to family and clan cohesion, such as conflicts between individual families, for example around food distribution or territory, or challenges to leadership, that require social constructs and narratives to provide the framework for resolution. The social and cultural infrastructure developed by these hunter-gatherers serves an essential guide in determining how individuals are expected to act, and what mechanisms are in place to ensure not only peace and harmony, but of survival of the individuals and the social group. Naturally, as environmental circumstances change, so do adaptations to the new set of realities evolve and engender resilience [3]. This exploration of resilience in a contemporary community of people who live as our ancestors did, is instructive as we look at the patterns of coping and resilience in our modern, highly industrialized societies.

PHYSIOLOGY OF THREATS TO SURVIVAL AND RESILIENCE

Dealing with threats to survival requires biological systems to identify and characterize the threats and then generate a corresponding response that will assure either removal of the threat or escape from the threat. The neurological infrastructure of this response resides in the hypothalamic-pituitary-adrenal axis which generates the hormonal releases that act on the physiological processes of various organ systems, such as the cardiovascular system, respiratory system, musculoskeletal system, endocrine system, immune system, and on the brain to execute the necessary responses for resilience, adaptation and survival [4]. In acute threats, the adrenergic reaction is activated which causes the heart to beat faster, blood pressure to rise, the blood flow to be diverted to the muscles where it is needed, and emotions to engage in an appropriate action that is characterized as the fright, fight, flight response [5].

Additionally, the corticosteroid system is activated to increase and maintain blood glucose levels because of the critical need for a source of energy, as well as activation of inflammatory and immune responses. Corticosteroids also act directly on the central nervous system (CNS), specifically the hippocampus, amygdala and frontal lobes stimulating arousal and memory, which are critical in determining action in times of stress. At a neurochemical level, serotonin levels are increased and play an active role in enhancing mood and positive behavior, which play a significant role in developing attitudes to overcoming threats.

The release of oxytocin in response to stress plays a key role in the activation of social considerations. Oxytocin release in childbirth and breast feeding promotes mother-infant bonding [6]. Oxytocin is also active in promoting positive social interaction and relationships and, during stress, is found to raise awareness about caring for others [7]. The ‘women and children first’ response in threats to group survival, is one such example of a biological imperative, because, teleologically, the survival of women and children assures the perpetuation of the species better than if men alone survive. Oxytocin may also play a role in the notion of self-sacrifice for the greater good of the family, clan or social group, as is required during grave threats to communal survival as often occurs during war.

It is important to note that psychological stresses evoke the same physiological reactions as actual physical threats to survival, with the corresponding adrenergic, corticosteroid, serotonin and oxytocin responses [8, 9]. The interplay between emotional stress, neurochemical and physiological responses, and the corresponding emotional reactions, represents a complex dynamic. Emotional reactions to dramatic and immediate threats or stresses, manifest as psychological states of anxiety, depression, obsessiveness, fear, anger, aggression, or even the paralyzing outcome of panic. The effect on the individual of these stresses and corresponding responses are influenced by many factors that play a part in resilience, including genetic, epigenetic, and environmental factors as well as the concept of ‘personality’ [10]. This dynamic not only plays out in determining responses to stresses, but also in modifying patterns of adaptation and resilience once the stressors have been removed and environmental factors become more favorable [4, 10]. It is this complex interaction that will be explored in this commentary.

GENETICS OF RESILIENCE

To understand the physiology and psychology of stress and resilience, it is helpful to consider genetic and epigenetic factors. Seminal work on patterns of maternal behavior in two groups of mother rats with their newborn pups illustrates the phenomenon of epigenetics [11, 12] (see Figure 2). One group of mother rats were nurturing, frequently engaged in the process of licking and grooming their offspring. Their offspring, in turn, grew up healthy and resilient and had offspring of their own, whom they licked and groomed, as they had been. A contrast group of mother rats were not nurturing at all, they neglected their offspring and did not lick and groom them much. Their offspring grew up to be malnourished, had high anxiety and were maladaptive in their behavior; when they, in turn, had their offspring, they likewise did not lick and groom their pups. This might lead the observer to presuppose that this phenomenon is genetic, that the pups are destined to carry on the intergenerational ‘gene’ for a pattern of maternal behavior. However, when the rat pups from the neglectful mothers were placed with the nurturing mothers and were licked and groomed during their newborn period, they grew up to be healthy; and, when they had pups of their own, they also licked and groomed them. The phenomenology of this finding was based on the epigenetic mechanism of switching genes on or off, triggered by external or environmental factors. In this case, the physical experience of the pups during the licking process initiated a cascade of biochemical events that resulted in the switching on of the gene for glucocorticoid receptor expression. The consequent physiological processes resulted in a profile of low glucocorticoid levels and low anxiety in the pups who were licked and groomed; in contrast to the increased glucocorticoid levels with a high anxiety level in the pups who had been neglected [12]. Thus, the physiological, psychological and behavioral characteristics of the mother instinct in the rat pups, once established, became the inherent set of genetic determinants of the future behavior in the pups. Although this is a rather simplistic rendition of the phenomenology of epigenetics, it nonetheless serves to illustrate how a physical experience in early life can have long term consequences even into the future generations.

Multiple genetic and epigenetic mechanisms relating to stress and resilience are expressed through the hippocampus and amygdala, which play out in the hypothalamic-pituitary-adrenal axis and noradrenergic, serotonergic and other neurochemical and neurohumoral pathways to affect response to acute and chronic stress [4]. The nature of epigenetics is a dynamic interaction between environmental stimuli and gene expression. The interaction between genetics, epigenetics and the environment not only plays a role in determining whether an individual may become resilient or not, but also in what symptoms and individual may develop, such as anxiety, depression, post-traumatic stress disorder (PTSD), or any other set of emotional and behavioral outcomes. Some of the biochemical factors under epigenetic influence involved in resilience include neuropeptide Y, which plays a role in regulating stress and anxiety, and brain derived neurotrophic factor (BDNF), which supports neuronal proliferation, differentiation and growth during development, and plays a major role in resilient adaptations to chronic stress. Furthermore, chronic stress may also result in shortened telomeres on the genes, which are also associated with reduced life expectancy [13].

Figure 2. Epigenetic mechanism phenomenology [12].

A review of other epigenetic and biochemical processes that have been identified can help to understand the variability within individuals or groups of individuals, but more importantly can assist in developing strategies to enhance resilience in children and hold the promise of developing preventive strategies and of reversing some of the long-term consequences of adverse childhood experiences [4].

REACTIONS TO STRESS IN CHILDREN

In children, physiological responses to physical, psychological and emotional stress result in the release of the same set of hormones as in adults, with the corresponding physical and physiological reactions in the brain, cardiovascular, hormonal, and immune systems. The singular and critical difference is that children are more vulnerable because their organ systems, physiological mechanisms, and brains are in the active process of growth and maturation. Therefore, the possibility of epigenetic modification of physiological response mechanisms, especially neurophysiological pathways, may be significantly altered with serious long-term consequences [14].

Not all stress that children experience is the same. Much depends on the timing, nature, severity, and duration of the adverse experience, as well as associated factors. Categorizing degrees of stress and their responses in children by levels is helpful in this context [14]. These degrees can be stratified into the mild, moderate and severe.

Mild, or mundane, levels of stress accompany inevitable events that may occur in an otherwise secure, everyday life and do not necessarily require major modification to life's journey. Examples include minor injuries or illnesses, or emotional reactions of separation or disappointment that occur in day to day life. The relatively low level of stresses in these examples results in low levels of physiological reactions with minimal permanent changes and merely the fine tuning of natural maturation.

Moderate levels of stress involve more dramatic events in life, such as a major injury or illness, a move from a familiar home, a family divorce, death of a familiar person, or a natural disaster. Physiological and psychological reactions and responses are correspondingly more dramatic and are more likely to become a significant and permanent part of the narrative of life for the child. However, with the support and nurturing of a concerned and involved parent figure, not only is the child expected to survive the ordeal, but to adapt in a positive way and gain from it, to be strengthened by it, even prepared with a greater likelihood of success in life.

Severe levels of stress, recognized, codified and studied as adverse childhood experiences (ACEs) [15], often referred to as toxic stress [14], are considered to involve psychological stresses related to more serious life episodes and experiences of chronic neglect, or elements of physical, emotional, verbal or sexual abuse of the child that is unrelenting and cumulative, in the absence of a consoling adult. These levels of stress inevitably result in the persistent and chronic release and circulation of neuroendocrine and corticosteroid hormones, which, while having a positive effect in the short term, have a potentially destructive effect in the long term. Persistent changes are found in the brain where the neural circuitry of the reward feedback is overwhelmed by the circuitry of fear, and the hippocampus and amygdala are reduced in size and functionally compromised [14, 16]. CNS disturbances may result in an increased risk of learning disabilities, ADHD, behavioral disturbances, PTSD, anxiety, depression, OCD and other mental health problems. Children who experience these negative effects to their CNS structure and function, are more likely to become pregnant as teenagers, have high risk pregnancies with an increased risk of premature births, engage in substance abuse and, if pregnant have infants with intrauterine exposure to the drugs (such as fetal alcohol syndrome), commit crimes, be incarcerated, and die young, often related to drugs or violence [17]. In the longer term, the neuroendocrine and immune systems are also compromised which can result in an increased likelihood of metabolic disturbances such as obesity and diabetes, as well as respiratory disturbances with an increased likelihood of asthma, and cardiovascular disturbances with an increased likelihood of hypertension and stroke, and autoimmune disorders. Consequently, there is an increased likelihood of intergenerational perpetuation of the cycle of health disparities [1, 2, 15, 17]. In addition, these organ system disorders can significantly reduce life expectancy [13, 14, 15].

It is therefore imperative that stress on children is minimized and resilience is promoted so that children live healthier lives with the promise of success in their future and for their offspring. Improving outcomes for children increases the likelihood that they will become active, participating members of society, and will make positive contributions to society when they grow up healthy in body and mind [1, 17]. James Heckman, Nobel Laureate in Economics, has demonstrated that investing in the promotion of child education and nurturing, especially among low resource families, translates into a real return on financial and social investment. These financial and social rewards come not only from the contributions that are made to society in practical and financial terms, but also the reduced

costs related to being less dependent on public welfare funds and to reduced likelihood incarceration. Using data from the Perry Preschool Program, Heckman and his colleagues estimate a total benefit of 7 percent per annum from all sources for each dollar spent on the preschool program, even counting the social costs of taxation [18].

RESILIENCE OF CHILDREN

Factors that predict positive outcomes for children who experience stress are 3-fold: the individual child's physiological and psychological genetic endowment and 'personality' [4, 10]; the nature and duration of the adverse experience; and, the availability support and encouragement of a concerned adult, who may be a parent or other parent figure [14]. The type and nature of support and encouragement that a child receives and the factors that mitigate the effects of the adverse experiences are critical in enabling the child to overcome the potential negative consequences of adverse experiences and go on to a promising future.

A loving, caring and nurturing parent is a primal need for a child. The early effects of this bonding relationship form the epigenetic underpinnings of a resilient child. The early work on human and primate maternal-infant bonding [19], and seminal work on the nurturing behavior of mother rats to their offspring [11, 12], has demonstrated that the impact of the intimate physical contact between a mother and her offspring has a lasting effect, protecting the child from the potential negative consequences of adverse experiences by stimulating the physiological and psychological processes that enhance resilience, in addition to being epigenetically transmitted to the next generation. Furthermore, ongoing supportive relationships that children have with their parents, or other significant adults in their lives, continue to promote resilience in the teaching of skills and strategies to overcome inevitable adverse challenges in life. Lessons about interpersonal relationships from parents, teachers, or with siblings and peers, nurture an ability to relate to other individuals and have lasting meaningful relationships as friendships and in marriage.

The teaching of moral and prosocial behaviors is also critical to the development of children, not only for them to become competent individuals but also to participate as contributing members of society. Participation in peer social groups at all ages provides the framework for teamwork and collaboration with others to accomplish a common goal. For example, participation in team sports and recreational activities has been shown to teach the importance of physical health and fitness, of working with others to achieve a common goal, and of the determination to win, and the ability to lose with grace [20].

The resilience of these children to adverse life experiences translates into their adult lives, not only by ensuring health and success, but also the ability to overcome adversities that inevitably arise through the lifespan. Adverse experiences and the stresses that accompany them are critical elements in the process of growth and development toward building strength and essential physical, emotional and social strategies to overcome adversity in the future. In turn, when these children become parents themselves, they are equipped to provide the same benefit to their offspring.

Questions arise as to what factors predict whether an individual child will succumb to adverse experiences, or if he or she will be resilient and adapt to the situation and work with it to overcome the challenge. There are a host of genetic, epigenetic and physiological factors

involved that not only help to explain the general reactions and responses that are associated with resilience, but also explain the high variability of individuals' responses and outcomes [4]. As an example, although the presence of a nurturing adult is critical in the process of adaptation, in overcoming adversity and being strengthened from the experience, there are children who have not had the benefit of a nurturing adult, but who have nonetheless have been able to grow beyond the adverse experiences and become functional and successful adults. While these successful adults are not necessarily without scars from their experiences, which inevitably shape their personalities, choices in life, nature of their lifestyles, and even how they handle their successes, less than 10% of children who experience ACEs will develop PTSD [21]. Furthermore, there is an ongoing dynamic interaction between the individual, other people and environmental factors that influence physiological operations that hold the promise of positively influencing neurochemistry and brain function towards greater degrees of survival, resilience, and functional success [4]. This is precisely where the promise for a positive outcome for a child who has experienced adverse experiences can be shaped by timely and appropriate interventions [18].

RESILIENCE OF ADULTS

The study of resilience in adults may be viewed from two different sets of circumstances. There are those individuals who had adverse experiences during childhood with the associated physiological and psychological consequences; and, there are others who have experienced adversity during adulthood such as, for example, adversity that commonly accompanies a traumatic personal experience, exposure to military conflict, or experiencing a natural disaster [22]. Rather than review the extensive literature on the subject of adults who struggled with adversity in their childhood and have had to live with the psychological and physiological consequences, we have chosen to offer personal narratives from three individuals who participated in the "12th Annual Break the Cycle Symposium on Resilience", as well as one narrative drawn from a published interview [23].

Natalie D Hernandez, PhD, MPH, is Assistant Professor, Prevention Research Center, Post-Doctoral Fellow, in the Center of Excellence on Health Disparities, Department of Community Health and Preventive Medicine, Morehouse School of Medicine, in Atlanta, Georgia. Hernandez describes her childhood in a poor and dangerous neighborhood, with a family who worked hard to support their children and thereby provided support, guidance and role models for their children. The lessons are that parental care and instilling values in their children by love and by the example of their actions, resulted in the determination and ultimate success of their child [24].

Started from the Bottom Now I'm Here: My Resilience Story

Growing up in the South Bronx, you are presented with many barriers and challenges. If you can make it there you can make it anywhere. I was in the cycle of environmental health disparities. You see, where I came from you have no choice but to be resilient. Here is some context because context matters. I grew up in one of the poorest districts in the nation. For a while we lived in a housing project known to locals as "Vietnam", due to the frequent violence that resembled a war zone. This caused a lot of stress among my family due to its

inadequate structure, exposures to drugs and violence. I was never allowed to go out and play because of these concerns. My parents were among the 60% of Bronx residents that had a high school diploma.

Growing up I saw my parents struggle to provide for me and my siblings. My dad worked two jobs and went to vocational school, while my mom stayed home to take care of us. They did their best to shelter us from our surroundings, by instilling the values of education and hard work. I escaped my environment by reading and excelling in school. I knew if I wanted out I needed the best education. I was constantly teased and ridiculed for being “a nerd”, but that only pushed me further. My first big opportunity came in my last year of junior high school. Due to my academic achievements I was asked to apply to a program that assisted academically-talented, underserved minorities gain access to some of the nation’s top independent schools in the country. I was accepted into the program, and that is where my story began to change. Although I was no-longer considered at-risk, I was now an outsider at the school and in my community. I was constantly having to hop-scotch between different cultural and linguistic spaces and different parts of my own identity—sometimes within a single interaction. It was a bittersweet time because I was attaining the best education but feeling more isolated and alone than ever. These feelings of isolation became worse as I applied to college and when I was enrolled. Although I had what every college would want in a prospective student I did not get into many colleges; additionally, when I did get in, my parents could not afford to pay for it. I had to manage five-plus classes, a job, extracurricular activities, events and workshops, studying, relaxing and other commitments. There was no wiggle room for messing up because as a low-income, minority, first-generation student. I was already identified as someone who will likely not graduate. It was a terrifying time because half the time, I didn’t even know what I was doing, or what I needed to do. These expectations and not knowing what to do followed me through my Master’s and PhD programs. Through these times I faced a host of behavioral and mental health issues. What got me through most of these challenges were my family and my passion for underserved communities. I now know that I had to experience these personal public health challenges to motivate me and make me good at what I do now. This is why my research is focused on low-income, underserved ethno-racial minority populations. This is why I now make it a priority to mentor students and be an educator at a Historically Black College and University.

I still face many challenges and struggle as a Latina researcher. I struggle with my identity, where I came from and the perceptions others have on me, especially in academia. But then I think back to that little girl who grew up in the South Bronx and had big dreams of helping others to have the opportunities she had. When the odds were against her, when people told her and still tell her she may not make it, she did. The opportunities I gained helped build me with skills and knowledge, but I also remember and remind myself of the strengths and talents I bring. Through my work I am contributing and dedicated to breaking the cycle that contributes to health inequities. My future career plans and goals with respect to health inequity are tied directly to my role as a researcher and a woman of color from the South Bronx. They are to strengthen health programs and policies, to reduce ethno-racial disparities, and to ensure that all people receive comprehensive, culturally appropriate, healthcare. The future health of America will be increasingly influenced by the success or failure of improving the health of ethno-racial minorities and I hope to be a part of the solution. This is what motivates me, and this is why I tell my story.

Lucy Hall, Founder and CEO of Mary Hall Freedom House in Atlanta, Georgia, describes her experience of being trapped in an intergenerational cycle of substance abuse, and only when she was to become a mother herself and faced the perpetuation of the cycle, did she find her faith and determine to change her lifestyle to care for and change the lives of her daughter and others for the better [25].

Transformation from Poverty and Substance Abuse to a Powerhouse of Support

I grew up surrounded by poverty and addiction, not knowing there was another way of life. At age 6 years, I lost her mother to alcoholism, and later lost two brothers to substance abuse. I was struggling with her own addictions when, at the age of 27 years, I gave birth to a daughter. Fearing that my daughter was destined to repeat the cycle of generational addiction that had plagued my childhood, I decided to get help and entered a treatment program for substance abuse.

Once I completed the recovery program, I was ready to start life afresh. The impression my mother left in my life inspired me to reach out to women who suffer from addiction and women with children. I decided that I wanted to help bridge the gap from troubled lives and help women become independent and self-sufficient. In

1996, I founded Mary Hall Freedom House (MHFH) in honor of my mother, Mary Hall. The mission of MHFH is to empower women to break the cycle of homelessness, poverty and addiction for themselves and for their children. The organization began in one apartment housing with two women. Today, MHFH is a leader in gender-specific behavioral healthcare, housing, and support services. Over the past 21 years, MHFH has blossomed into a vital community asset, with a dedicated staff of 65 who serve nearly 600 women and children annually. Eight of MHFH's staff are former graduates of the program—living proof of the power of the organization's programs and services.

Today, my dream has become a reality with MHFH. Through a community of sisterhood, I coach women to free themselves from the past and live every day for the future. Over 10,000 women and children have achieved recovery through MHFH since its founding in 1996. Everyone here knows that G-d is really the head of this agency. He has made it possible for us to minister to the women, children, and families sent through our doors.

Jessica Spraggins MPH, CCHP, is a health communications specialist in the Division for Heart Disease and Stroke Prevention at the Centers for Disease Control and Prevention (CDC). Ms. Spraggins relates how she grew up with almost every stressful experience possible and suffered for much of her life from the effects of the Adverse Childhood Experiences. Because of her spirit of determination, she became socially successful, but remained psychologically imprisoned by her past. Then one day she had an epiphany and resolved to change her personal life and has now become a successful advocate for children who are suffering as she did [26].

Jessica Spraggins – from ‘Welfare Brat’ to Advocate

My name is Jessica Spraggins and I am a Health Communications Specialist with the Centers for Disease Control (CDC). I have a BA from The George Washington University and MPH from Yale. I came from a dysfunctional, abusive home. I am also a survivor of childhood rape. I am one of nine kids. My parents had five children and adopted four more children out of the foster care system. We switched schools and emergency rooms often, usually when the staff at either facility ‘had the nerve’ to question how much and what type of attention we were getting from our mom. We were welfare brats.

As a welfare brat you move to the places that have available section 8 housing or that would accept vouchers. This includes drug houses. You’d learn to pick the needles up off of the playground before letting the younger kids come out to play. The best places were the ones out in the country, because even if they were full of rats and roaches and the well water stunk of sulfur and was barely drinkable, we could escape outside where our imaginative play was a hundred times better than the hitting, yelling, or ignoring that we would experience inside.

The movie “Mommy dearest” came out when I was a little kid. My best friend had watched it and was telling me how the mom in this movie was so scary and mean and awful, she even hit her daughter with a wire hanger! So, I had to watch this movie and see this awful, horrible, terrible mom. Except when I watched this movie Joan Crawford didn’t seem that awful to me, she seemed like my mom, only with more money, a cleaner house, and fewer cigarettes. So, in my little 1st grade mind I was really puzzled as to why my best friend thought this movie mom was so terrible.

I first read “I know why the caged bird sings” by Maya Angelou when I was about 9 years old and I had heard some 8th grade girls on the school bus talking about the scandal in the book. Within these pages Maya Angelou describes her rape as an 8-year-old girl. She plainly talks about the man who assaulted her, the justice system that failed her, the family that surrounded her, and her escape into books. I thought: how can THAT be the drama? It happens all the time. That same thing happened to me when I was even younger than Maya and nobody made a big deal about it.

Abuse and poverty can shape you in ways that you don’t even realize as a child. For me it pushed me to work harder, to want more, and to be the exact opposite of the little girl I was growing up. So, I worked hard, I got an education, became a professional, became a mother and a wife and told the right stories and did the right things and gave of myself, while smiling and carrying my babies in their ergonomically correct Maya wraps.

But then I hit a point in my life where it got hard to keep smiling and to get out of bed every day to keep doing the “right” thing. In November 2012, I called the police for the first time in our marriage on my then-husband after he threatened me *again*, broke down our back door *again*, and shoved me around *again* all while

in a drunken rage *again*. That was the day that I had had minor surgery to get my tubes tied and our youngest son was eight weeks old. The police officer that showed up that night was kind, but he asked me the most brutal questions. Has he done this before? Yes. Was it reported? No. Has he broken anything else in the house? Yes. Was it reported? No. Has he physically or sexually assaulted you before? Yes. Was it reported? No. Has he been arrested before? Yes. Was it from something you reported? No.

As hard as I worked to be better than the life I grew up in, I had spent eight years in an abusive marriage with an alcoholic drug user. I had no self-esteem and felt no self-worth, and I was more than 100 pounds overweight. I was miserable and wanted to run away from my own life, so I knew that for my sake and the sake of my children I had to figure this out.

I read about the work that CDC was doing on the adverse childhood experiences (ACE) study. The ACE Study findings suggest that certain childhood experiences are major risk factors for the leading causes of illness and death as well as poor quality of life. There is even a questionnaire that grades you 0-10 on how messed up your childhood was. I took it and I got a 9, which included a statistically greater risk for heart disease, stroke, and a host of other chronic diseases. What I realized, there and then, was that I had to find a way to take control of my life.

I have found with kids that grew up with little to nothing they seem to sway one of two ways. Either growing up with a sense of entitlement, as in “I had nothing, so the world owes me everything”, or growing with a sense of gratitude, as in “I had nothing, so I am thankful for what I do have”.

Most of the kids that I grew up with, including some of my siblings, chose the path of entitlement. They had it hard, so they wait, and they expect, and they resent and, while they do that, they miss the opportunities that pass them by, thus perpetuating the cycle that defined their life of poverty and abuse.

The other path of gratitude seems to be less popular, mostly I think because it requires action and initiative. I have to say, when I look at how I ended up here instead of there, I think it comes down to some very conventional, not at all exciting ways of pulling through. I have also had some amazing people support me during this process and they have asked me how I seem so normal. Though I certainly don’t feel normal I know what they mean.

This has been a personal journey for me. But it is also a story showcasing a greater public health issue. D. Robert Block, former president of the American Academy of Pediatrics said that: “Children’s exposure to adverse childhood experiences are the greatest unaddressed public health threat facing our nation today.” My story of resilience doesn’t have to be the exception. With the science that we have on ACEs and the information that we are learning on resilience every day, positive outcome from childhood trauma can and should be the norm.

Nate Awan is an African-American man who grew up in poverty in a rough neighborhood and became rough himself, then found himself in prison. When he realized the path he was on, he was determined to make a better life for himself. He took advantage of the opportunity to enroll in a rehabilitation program, studied and on release from prison, became a pipefitter. He is now gainfully employed in a job he likes, supports a family and is a steady citizen contributing to society.

Nate Awan: The Pipe Fitter [23]

From the job site in Roxbury where he works as a union pipe fitter, Nate Awan can see the building that once housed the Phillis Wheatley Middle School, from which he was expelled for fighting and other misbehavior. “That was back in my knucklehead time,” he said.

The fifth child of an overwhelmed single mother, Awan was kicked out of four schools and took a bullet in the shoulder before going to prison at 18 years for trying to shoot a rival gang member. While serving a three-year sentence, he resolved that he would change his fate.

With the help of a former prosecutor who took an interest in his rehabilitation, Awan found his way into Operation Exit, a program founded in 2014 in which the city of Boston partners with unions to channel residents with criminal backgrounds into the trades. Having sampled carpentry, sheet-metal work and other options, Awan, who had always been fascinated by welding but doesn’t like heights, chose pipe fitting over iron work.

There’s plenty of politics in the building trades, but there’s also an ethos of craft meritocracy. “It’s not what you look like, it’s what your clevis hangers look like,” Awan said, referring to the brackets used to support

pipes. “All at the same level, nothing crooked. It’s about your work ethic.” He’s already planning to get his 5-year-old son into the local when he’s old enough.

Awan, who is 28 years and currently a second-year apprentice making \$30 an hour plus benefits, can become a journeyman in three years, and he looks forward to continuing up the scale of seniority and pay toward the top rate of \$50 or so an hour. He still lives near the Four Corners section of Dorchester where he grew up, but he’s shopping for a house outside the city. “You come from no money for food, nothing, to where you’re buying a house, buying a car,” he said. “Your son needs a school uniform, you can get him one.”

Boston’s mayor, Martin Walsh, intends Operation Exit to enable this kind of transformation of prospects and consciousness. Walsh, who also grew up in Dorchester and had his own troubles (a bullet grazed his leg) before putting his life on course in the building trades, says, “We’ve had 80 graduates come through this program, and we’re expanding from the building trades into coding and culinary arts. Some of these guys were impact players on the street. It has an effect.”

Programs that reduce crime by connecting offenders and potential offenders to meaningful work are getting more attention across the country. Some, like Operation Exit, focus on re-entry after prison; others, like the Chicago CRED initiative recently started by the Emerson Collective and Arne Duncan, the former US secretary of education, try to reduce gun violence by teaching job and life skills to young men adrift from both school and the labor market. It takes a significant investment of time and resources to shift a life from a dead-end trajectory to a viable future in this way, but Awan testifies to the approach’s effectiveness. “I’m no surgeon or big-time prosecutor,” he said, “but for me — a product of his environment, taken from my mother at 9 years, incarcerated at 18 years, sweeping and mopping in the hole in prison for 19 cents an hour, living like a peasant — this here is a lottery ticket.”

RESILIENCE IN A GLOBAL CONTEXT

History is replete with examples of personal and collective adverse experiences and tragedies that shaped humans’ personal and collective understanding of adaptation and resilience. An example of an individual in a global community who embodies the spirit of adaptation, resilience and ultimate success is Nelson Mandela (1918-2013). Mandela grew up in rural South Africa in a tribal culture. He went to school and became a lawyer. His sense of justice focused on the inequity and injustice of Apartheid South Africa, so he became an activist and eventually, out of frustration, became involved in the armed resistance movement. He and his co-conspirators were caught, arrested, tried, convicted and imprisoned on Robben Island, far away from civilization. His intellect, his pride and his sense of justice did not fail him. After 27 years on this prison island he was released and went on to become the first President of the new multiracial South Africa. His spirit of courage, steadfastness and magnanimity resulted in a relatively peaceful political transition process while many other countries in Africa shed their colonial pasts with bloody struggles. His resilience and his achievements justifiably earned him the Nobel Peace Prize.

Other examples of resilience can be found in one of the defining global events of the 20th Century in the World War of 1939-1945 and the Holocaust [27]. Survivors of these horrors embody the spirit of resilience and have made contributions to society in significant ways. Elie Wiesel (1928-2016), whose detailed descriptions of his experiences and observations during the Holocaust, most notably, his first book “Night” [28], as well as novels, essays and speeches depicting the suffering endured by so many of his fellow Jews and other persecuted people, helped shape the post-war moral thinking in terms of understanding, compassion and justice. This earned him a well-deserved Nobel Peace Prize. Another survivor who described his experience in similar circumstances was Viktor Frankl (1905-1997), who captured the elemental spirit of survival in the title of his book “Man’s search for meaning” (the original title was “From death camp to existentialism”) [29], enriching the field of psychology and providing us with a deeper understanding of resilience. While in the concentration camps,

Frankl noted that there were people who were determined to go on living regardless of the circumstances and those who had ‘given up’. Based on his observations and his own personal experiences, he developed the psychiatric approach of Logotherapy, which embodies the notion that finding meaning and purpose in one’s life is the most important and powerful motivating force to continue to go on living [30].

In the aftermath of the suffering and horrors of World War II, the world body came together to establish the United Nations and craft a Charter of the United Nations and Statute of the International Court of Justice to promote human rights, freedom, equality and justice and a check on preventing such atrocities from ever happening again [31]. These noble thoughts, statements and actions have served to improve the health and stability of an ever-changing, fractious and, at times, volatile world. The Millennium Development Goals 2015 [32] and the Sustainable Development Goals 2030 [33] are testaments and guidelines to demonstrate how the world body strives to continue to reduce health disparities by promoting health equity and striving to improve the health of all the people in our global village.

MAKING A POSITIVE DIFFERENCE

In order to make the world a better place, we need to make sure that all children who grow up in it are equipped to deal with the challenges that come their way, at a personal level, at an interpersonal level, at a community level and at a global level. Obviously, children need adequate nourishment and protection to survive, but we must also provide children with the necessary emotional support and guidance that will enable them to survive and adapt to challenges that they may encounter.

The following are some distillations of strategies to promote resilience:

- Assure that every child is loved and protected from physical and emotional harm
- Provide support for parents, particularly those who are stressed [34]
- Provide a good education for children about life and the necessities for survival and success [18]
- Promote good eating habits and exercise to maintain good health
- Encourage children to engage in team sports and activities to help learn how to work together whether you win or lose [20]
- Provide for a sense of community in developing personal relationships with individuals and with groups of individuals
- Offer a moral compass as a vital necessity for a shared communal life
- Offer a role model on how to help others in distress
- Promote an understanding of the larger world stage will help us learn to live together with people of other cultures and instill a sense of responsibility in environmental stewardship
- Provide guidance and strategies on how to deal with hardships in a constructive manner [35]
- Cultivate a spirit of optimism which will lead to constructive approaches to life’s challenges
- Demonstrate humility and encourage a sense of humor

For those children who have experienced adverse childhood events, there is an additional set of recommendations to improve resilience and reduce the likelihood of negative long-term consequences [36]:

- Treat maternal mental health problems
- Promote self-care skills and routines
- Assure a positive and secure home environment which may involve foster care
- Provide early intervention for children
- Enhance trauma understanding
- Offer counseling or peer-based support groups to the children and their families
- Provide a Pediatric Medical Home for the children and their families [37, 38]
- Promote strategies and programs to Break the Cycle of Health Disparities [1, 17]

CONCLUSION

Up to almost 50% of children will experience an adverse life event. Most, however, are resilient and adapt to the experience, and may even be strengthened by the experience. There are many, however, who are likely to experience serious long-term consequences that manifest in the emotional and mental health concerns such as anxiety, depression, OCD, and PTSD among others. These conditions seriously affect the child's ability to function, and may persist into adult life with adverse experiences for them and their offspring and thus perpetuate a cycle of health disparities. Children who experience ACEs may also develop physiological and immunological disturbances that may manifest as adverse health effects which affect quality of life, productivity and happiness, and shorten their lifespan.

Our responsibility is to improve our understanding and awareness of the impact of adverse physical, emotional, social, economic and environmental factors have on children, especially if they are cumulative and have a basis in poverty. With increased awareness, our role is to implement strategies to prevent these adverse events, promote resilience in children and their families, and support and assist children and their families who are struggling with the outcomes of ACEs. With help in mitigating the effects of these adverse events and guidance on overcoming them, children can gain the necessary self-confidence, self-respect, self-esteem and skills to go on to become successful and contributing members of society.

Chapter 258

MATERNAL DRUG USE AND THE SEVERITY OF NEONATAL ABSTINENCE SYNDROME

***Pratibha Agarwal, MD, MPH, Beth Bailey, PhD,

Johnson City, Tennessee, USA

ABSTRACT

East Tennessee and Middle Appalachia is the epicenter of the prescription drug epidemic, with approximately 15% of women giving birth at our institution documented as suffering from drug addiction. Objective: In this chapter we describe our sample of women giving birth to infants who were drug exposed and experienced Neonatal Abstinence Syndrome (NAS) and to determine the maternal and neonatal factors associated with the severity of NAS as measured by the length of stay (LOS) in the Neonatal Intensive Care Unit (NICU). Methodology: This was a retrospective chart review of 73 infants diagnosed with NAS and treated in the NICU. We conducted bivariate analyses and multivariate modeling (least squares regression with backward elimination) of the significant variables ($p < .10$) against the infant's LOS. Results: The mean LOS for infants with NAS was 17.7 days ($sd = 11.6$); 75.3% received nonpharmacological and 86.3% received pharmacologic (morphine) treatment. Of 73 women, 53.4% had a history of mental illness; 53.4% smoked >5 cigarettes per day in last trimester; 89% were taking buprenorphine, 9.6% had cord tissue positive for benzodiazepine. Term infants had 2.3 day longer LOS on average ($p = 0.027$) compared to preterm infants; infants exposed to benzodiazepines had 12.7 day longer LOS on average ($p = 0.07$) and prenatal exposure to >5 cigarettes per day in last trimester increased the hospital stay by 6.4 days ($p = 0.022$). Conclusion: We found that exposure to benzodiazepines and cigarette smoking were associated with an increased LOS.

INTRODUCTION

Over the last decade, use of prescription opioids such as morphine, hydrocodone, and oxycodone for pain during pregnancy has increased substantially [1]. Tennessee has the second highest rate of opioid use in the country [2] with use concentrated in the Appalachian regions of the state and neighboring states [3]. Use of these substances often continues into pregnancy [4], potentially impacting the exposed fetus. Misuse of prescription opioids contributes to a substantial portion of the growing burden, with nonmedical use of prescription opioids increasing 162% over the last decade and surpassing all drugs other than marijuana [5]. Among rural pregnant women, prescription opioids are the most frequent drugs of abuse [6]. In addition, for those who enter pregnancy using high levels of prescription opioids or illicit opioids, medically assisted treatment (MAT) approaches involving prescribed opioid medications, methadone or buprenorphine which block opiate withdrawal symptoms, have the potential to affect the fetus negatively [7].

Neonatal abstinence syndrome (NAS) is a drug withdrawal syndrome that can occur in newborns after exposure to a variety of drugs, prescribed or illicit. The signs and symptoms of NAS are both broad and multi-system, with the more common symptoms affecting the central nervous and gastrointestinal system. NAS is diagnosed by following exposed infants for 4-5 days and monitoring for withdrawal symptoms. About one third of exposed infants develop symptoms severe enough, as rated by the Finnegan Scoring Scale, to warrant the diagnosis of NAS [8]. Based on the severity of the clinical signs, infants may need non-pharmacologic (swaddling, breastfeeding, quiet environment, etc.) and/or pharmacologic treatment (primarily morphine or methadone but other medications are also used). The management of drug withdrawal in neonates can necessitate prolonged stays in the Neonatal Intensive Care Unit (NICU) that can lead to a huge financial burden on the health care system, primarily borne by state Medicaid programs. A study done by Patrick, et al. showed the mean cost of a hospitalization for NAS was \$53 000 per newborn [9]. Over a period of four years, from 2009 to 2012, the hospital charges for NAS have increased from \$732M to \$1.5B ($p < 0.001$) [10]. Also of importance, long NICU stays impose a heavy emotional burden on the family.

Using Tennessee Medicaid claims data, Patrick et al. [11] demonstrated that the likelihood an infant exposed to opioids in utero would be diagnosed with NAS increased with exposure to a higher cumulative opioid exposure of short-acting vs. long-acting opioid preparations, number of daily cigarettes smoked, and exposure to selective serotonin reuptake inhibitors (SSRIs) [11]. However, while some factors have been identified that predict the severity of withdrawal symptom and resulting length of stay for the neonate, a comprehensive profile of demographic and clinical factors have yet to be described. The objective of our study was to describe a sample of women from Central and Southern Appalachia giving birth to infants who were drug exposed and experienced Neonatal Abstinence Syndrome, and to determine the maternal and neonatal factors associated with the severity of Neonatal Abstinence Syndrome (NAS), as measured by the length of stay in the Neonatal Intensive Care Unit (NICU). Knowledge of these factors will help us identify the high-risk population and tailor the interventions accordingly early in the pregnancy to reduce the incidence and severity of neonatal abstinence syndrome.

OUR STUDY

This study was conducted within a regional health system with six delivery hospitals in Central and Southern Appalachia. All newborns admitted to a Neonatal Intensive Care Unit (NICU) with a diagnosis of NAS between the years 2011 and 2016 were eligible for study inclusion. There were approximately 500 infants in this period that were exposed to opioids. This study reports on the first 73 eligible infants selected and abstracted across the five year sample. A retrospective chart review was conducted, and relevant information was manually extracted from the electronic health record from the delivery and newborn hospital stay.

VARIABLES

The specific variables were abstracted from the electronic health record that included multiple sources including prenatal records, information reported by the patient during the intake nursing assessment, prenatal care physician documentation, and delivery record and hospital stay summaries. Variables constructed from multiple sources within the medical record are explained below. Results of maternal and infant urine drug testing, and cord tissue analysis, were also collected. The primary outcome of interest was infant length of hospital stay, utilized as a proxy for NAS severity. Recorded in days, this variable represented the length of time between admission to NICU and hospital discharge.

Primary predictors of length of stay were classified as variables representing demographic and medical characteristics of mother and newborn, and variables related to prenatal substance exposure. For newborns, we collected gestational age in weeks based on estimated due date from ultrasound, and weight at birth in grams. Additional infant variables collected included whether the infant received breastmilk (yes or no) and types of treatment for NAS (pharmacologic and non-pharmacologic). For mothers, we collected basic demographics including age in years, marital status (married or non-married), highest education level (less than a high school diploma, high school diploma only, and more than a high school education). Whether the mother received income-based government medical insurance (i.e., some type of Medicaid) was indicated and the final dichotomous variable (government or no medical insurance vs private insurance) was used as a proxy for income. Number of previous births (grouped as any vs none) and delivery type for this birth (vaginal vs cesarean) were also recorded. We also abstracted the following maternal variables as potential predictors: Maternal mental health problems (yes/no, yes if the mother reported being diagnosed with or reported receiving a medication for a mental health condition), hepatitis C diagnosis (yes vs no), and use of buprenorphine as medication assisted treatment during pregnancy (yes vs no).

Substantial information about maternal substance use during pregnancy was extracted and multiple measures were created. Tobacco use was coded as any versus none (yes/no). The degree of smoking was assessed as comparing those who smoked at least five cigarettes per day in the final month of pregnancy versus those who did not. For use of buprenorphine, other opiates (prescription or illicit), and benzodiazepines, two variables were constructed for each. The first was an “any evidence” variable that was positive if any source of information indicated use of that drug during pregnancy. Sources of information included documented

prescription for that type of drug, self-report during prenatal care or at delivery, positive maternal urine drug screen during pregnancy or at delivery, positive newborn urine drug screen, or positive cord tissue test. A second variable for each drug type was also constructed and was positive only if the cord tissue was positive for the drug, possibly indicating a higher and later level of exposure. Finally, for buprenorphine use, a third variable was constructed representing amount of use (<10mg/day vs 10+ mg/day). Reliable data was not consistently available to construct amount of use variables for benzodiazepine or other opiate use.

STATISTICAL ANALYSIS

Descriptive statistics were used to detail sample characteristics. Independent groups t-test were used to examine bivariate relationships between each individual potential predictor and newborn length of hospital stay. Finally, least squares multiple regression analysis was used to develop the best prediction model for infant length of stay. Backward entry of potential confounders included maternal age, maternal marital status, maternal education, maternal insurance status, parity, infant gender, delivery type, gestational age at birth, infant birth weight, and maternal mental health status. Substance exposure variables significant ($p < .10$) at the bivariate level were forced entered in the final step (buprenorphine exposure not included due to high rate use/lack of variance in this mostly MAT sample).

OUR FINDINGS

The infants in the study sample, all of whom had prenatal drug exposure and were diagnosed with NAS, averaged 17.7 days (sd = 11.6). for their newborn hospital stay. Additional sample characteristics are presented in Table 1. Overall, rates of low birth weight and preterm birth were low for our NAS sample. Most of the infants received both pharmacologic and non-pharmacologic treatment for NAS. Data available on the mothers revealed that the vast majority were unmarried and relied on government health insurance and 34% had not graduated from high school. Nearly four in five mothers had given birth previously. More than half experiencing a mental health condition, and more than one third had been diagnosed with hepatitis C. Nearly all had received buprenorphine as part of treatment for opioid addiction during pregnancy.

The associations between infant length of stay and newborn and maternal characteristics are presented in Table 2. Higher levels of buprenorphine exposure (as indicated by a positive cord tissue) increased length of stay by nearly five days, while higher levels of tobacco exposure (as indicated by 5 + cigarettes per day in the final month of gestation) increased length of stay by over four days. The strongest predictor was higher levels of benzodiazepine use (as indicated by positive cord tissue), which increased length of stay by nearly 10 days. Finally, length of stay was increased almost four and a half days for newborns whose mothers had a mental health condition.

Table 1. Demographic characteristics of sample

	Percentage
Newborn characteristics	
Gender (male)	60.3%
Gestational age (preterm < 37 weeks)	13.7%
Birth weight (low birth weight < 2500g)	15.1%
Delivery type (vaginal)	65.8%
Breastfeeding status (being breast fed)	41.1%
Received pharmacologic treatment for NAS	86.3%
Received non-pharmacologic treatment for NAS	75.3%
Maternal characteristics	
Background	
Age (< 25 years)	26.0%
Unmarried	72.6%
Highest education level	
<High school graduate	34.2%
High school graduate only	38.4%
Beyond high school	27.7%
Medical insurance (government, income based)	87.7%
Parity (1+ previous births)	79.5%
Medical	
Mental health diagnosis	53.4%
Hepatitis C	37.0%
Received medication assisted treatment	97.3%
Substance Use	
Any tobacco use during pregnancy	90.4%
Tobacco use 5+ cig/day final month of pregnancy	53.4%
Any buprenorphine use during pregnancy	89.0%
Cord tissue positive for buprenorphine	61.6%
Buprenorphine amount (of those receiving it)	
<10 mg/day	53.1%
10 + mg/day	46.9%
Any benzodiazepine use during pregnancy	34.2%
Cord tissue positive for benzodiazepine	9.6%
Any opioid (non-MAT) use during pregnancy	97.3%
Cord tissue positive for opioid (non-MAT)	5.5%

N = 73

Table 3. Regression results predicting newborn length of stay**

Predictor	Unstandardized coefficient	Standardized coefficient	p
Gestational age at delivery (weeks)	2.33	.353	.027
Infant birth weight (100g)	-.50	-.223	.149
Prenatal benzodiazepine exposure + cord tissue	12.69	.325	.007
Prenatal exposure to 5+ cig/day final gestational month	6.40	.274	.022

**Results are from backward entry of potential confounders: maternal age, maternal marital status, maternal education, maternal insurance status, parity, infant gender, delivery type, gestational age at birth, infant birth weight, and maternal mental health status. Substance exposure variables significant ($p < .10$) at the bivariate level were forced entered in the final step (buprenorphine exposure not included due to high rate use/lack of variance in this mostly MAT sample).

Overall results of the regression model predicting newborn length of stay are presented in Table 3. Of the background and medical factors, only gestational age at delivery remained a significant predictor after inclusion of other significant predictors. In this case, greater gestational age at delivery predicted longer hospital stay, with each additional gestational week increasing length of stay by 2.3 days. Both having a positive cord tissue for benzodiazepines and prenatal exposure to five or more cigarettes per day in the final month of gestation also significantly predicted newborn length of stay after control for all other significant predictors. Specifically, exposure to this level of tobacco in the final weeks of gestation increased length of stay by over six days, while having a cord tissue sample positive for benzodiazepines increased newborn hospital stay by an average of twelve to 13 days.

DISCUSSION

In our study of 73 women in Central and Southern Appalachia, we found that women were not young nor first time mothers which is consistent with the findings from other studies [12]. The average age of women was 28.3 years with a mean parity of almost two (indicating most of them had been pregnant at least twice). Their lives were characterized by disadvantage and/or abuse, as exemplified by the high rate of relationship instability (less than a third were married), low educational levels (only a quarter of the women were educated beyond high school) and high rates of poverty (the vast majority of women had government health insurance compared to 50% of births nationally). Almost all of the women reported some smoking and about half reported smoking over five cigarettes per day in their last month of gestation. Many women had a history of poly drug use in addition to medically assisted therapy for opioid abuse. This was evidenced by the fact that all infants in our sample were exposed to both opioids and other drugs.

We found that exposure to smoking in the last trimester can prolong the length of hospitalization in neonates with NAS. Similar findings were obtained in a study done by Jones et al. [13]. They demonstrated that there is a positive association between the average number of cigarettes smoked and several poor neonatal outcomes; for each additional cigarette smoked there was an increase of about 6% in the total amount of morphine needed to treat the withdrawal symptoms, 4% increase in the number of days of being on medication and 3% increase in the length of hospitalization [13]. Another important predictor of total length of hospital stay is the use of benzodiazepine along with opioids. Two other studies

have established this association but unlike our study, the infants in these studies were exposed to methadone and not buprenorphine [14, 15]. The finding of longer length of stay in infants with greater gestational age is also in line with the existing literature. Gibson et al proved that among infants who required pharmacologic treatment for NAS, term infants were treated longer than preterm infants [16].

Figure 1. Cycle of environmental health disparities.

NAS can be prevented or its severity reduced through primary and secondary prevention strategies. A primary prevention strategy to prevent pregnancy in women who are opioid dependent or in Medically Assisted Therapy. Studies have shown that in opioid users, more than 85% pregnancies are unintended (as compared to approximately 50% in the general population) [17]. An effective strategy is to reach out to women in MAT and improve access to long-acting reversible contraception (LARC) methods to decrease the rate of unplanned pregnancies [18]. We found that heavier cigarette smoking (>5 cigarettes per day in the last trimester) were associated with an increased LOS, our proxy for the severity of the NAS episode. Secondary prevention strategies to reduce the severity of NAS should be targeted at reducing smoking and poly drug use during pregnancy. Studies have shown that the use of an escalating voucher programs for smoking cessation in pregnant women with concurrent opioid abuse helped the women reduce their smoking and improve birth outcomes [19]. Health care providers in our area should identify women with smoking and substance abuse early in pregnancy and provide individually tailored programs aimed at reducing the smoking rates during pregnancy. Lastly, we found that the use of benzodiazepines with opioids greatly increased the severity of NAS. Pregnant women on MAT should be counseled to avoid benzodiazepines and clinicians caring for these women should consider using alternatives to benzodiazepines while treating mental health disorders in pregnant women with opioid addiction.

Using “Break the cycle” framework (see figure 1) help us identify and tie together the factors that contribute to the poor outcomes we document in our study. The women in our sample experienced multiple social and emotional disadvantages as evidenced by their poverty, low educational achievement and relationship instability. Life course theory posits that cumulative experiences can determine an individual’s future health and development [20]. Cumulative disadvantages and stress increase the risk of poor life outcomes, mental health problems and addictions, which we saw in our sample. Therefore, primary prevention measures to prevent NAS should target the root causes of maternal drug use such poverty, inadequate education, relationship stability and mental illness. The women in this group generally face social exclusion and economic and environmental inequalities which eventually lead to unhealthy behaviors such as substance abuse and cigarette smoking. Their children are raised in the same adverse social conditions leading to similar outcomes and thus the vicious cycle of disadvantage perpetuates. To break this cycle, we need address the larger social and structural issues leading to economic disadvantage and isolation in Appalachia. Substantial research exists to show that evidence based interventions early in life to support the social, emotional and cognitive development of the child and support the mother pay significant dividends in adult life that includes higher education levels, and lower rates of unhealthy behaviors such as smoking and drug use [21, 22]. Programs such as high quality preschool and family home visiting and support services such as the Nurse Family Partnership should be funded to help prevent the Cycle of Disadvantage that result in maternal drug abuse and neonatal abstinence syndrome.

The current study is not without limitations. First, it was retrospective, and thus was limited by the availability of data abstracted from electronic health record. However, use of electronic health record data did provide for a rich data set by allowing the construction of variables from multiple data sources. Another study limitation was that the sample size was small and represented only our initial chart reviews. However, the study did benefit from a sample that was representative of a wide geographic area. Lastly, a further limitation of our study is that we lack information on alcohol ingestion by the women in our study. However, alcohol ingestion, while very important for long-term child outcomes, may not have a major impact on our major outcome of NICU length-of-stay.

CONCLUSION

Maternal use of prescription or illicit opioids is rooted in women’s life histories characterized by material disadvantage and multiple vulnerabilities such as mental illness and relationship instability, smoking and poly drug abuse. Primary prevention efforts should target the root causes of maternal drug use including poverty, inadequate education and mental illness as well as helping women dependent on opioids prevent pregnancy. Secondary prevention interventions to reduce the severity of NAS should be targeted at reducing smoking, opioid addiction and poly drug use prior to and during pregnancy.

ACKNOWLEDGMENTS

This research was part of the “Break the cycle” program, a collaborative interdisciplinary research and training program and annual conference at Emory University funded by the cooperative agreement award number 1U61TS000118-05 from the Agency for Toxic Substances and Disease Registry (ATSDR). We thank our colleagues from Southeast Pediatric Environmental Health Specialty Unit (PEHSU) who provided insight and expertise that greatly assisted the research. We thank other participants and the reviewer committee for comments that greatly improved the manuscript.

Chapter 259

MOTHERS IN PRISON

***Tatenda Mangurenje*, PhD Student

Department of Anthropology, Emory University,
Atlanta, Georgia, USA

ABSTRACT

The aim of this chapter is to investigate how the socio-environmental conditions that lead to poverty are associated. The objectives: 1) to draw attention to the incarceration experience of, women and children; and 2) to examine whether incarceration among Georgia women is associated with child behavioral health outcomes. Data was drawn from secondary analysis of a clinical sample of 40 children receiving services from the Emory Neurodevelopmental and Exposure Clinic (ENEC) in Atlanta, Georgia in 2017. Results showed increased levels of internalizing and externalizing behavior problems amongst children of incarcerated mothers compared to population norms. However, we also showed high rates of internalizing and externalizing behavior problems in a contrast group, which was comprised of children who were separated from their mothers at birth due to maternal drug use. Qualitative results suggest that incarcerated women and women whose children were removed from their custody at birth had similar life history trajectories leading to similar outcomes. Qualitative results also revealed that children in both case and contrast groups were exposed to stressful environments either in utero and/or while in their mother's care. Collectively, these results suggest that although maternal incarceration is a stressor, the adverse early social environments have an equally negative effect on internalizing and externalizing behavior problems in children. In order to break the cycle of social-environmental health disparities, future research and interventions should focus on how to protect these vulnerable children from the factors that lead to maternal incarceration and its consequences.

INTRODUCTION

The last three decades of the United States' (US) war on drugs have seen an increase in incarceration and concern about its effects. Much of the focus has centered on the vulnerability of men, particularly young men of color, with little attention paid to the possible impacts of this war on women and children [1, 2]. Although males constitute most of the US prison population, there are an increasing number of female prisoners [3]. According to the American Civil Liberties Union (ACLU), women constitute the fastest growing segment of the American prison system [3]. Beginning in 1985, female incarceration rates have increased twice as much as those of their male counterparts [3]. As such, women constitute a growing but hidden segment of the American criminal justice system.

This gender bias underscores the need to study further the effects of incarceration on female inmates. The limited body of existing research on female inmates demonstrates that, similar to their male counterparts, women also are likely to experience the poor physical and mental health outcomes and worse self-reported health, which has been associated with incarceration [4-8]. Additionally, children might be at risk because approximately 70% of women in prison have children under the age of 18 and roughly 62% of these women were their children's primary caregivers and financial providers at the time of their incarceration [9-11]. Parental incarceration can negatively impact outcomes such as housing and schooling; indeed, evidence is emerging that children with incarcerated mothers are more likely to live in poverty, report poor academic performance, abuse drugs and develop mental health problems such as depression and anti-social behavior [12-14]. These children are also more likely to be incarcerated themselves later in life [12, 15]. The adverse effects of incarceration are suggested to be greater when mothers instead of fathers are incarcerated, since mothers are usually the primary caregivers [9, 10, 16].

Incarceration is a critical issue in understanding the impact of these children's separation from their mothers. Typically, incarceration is measured at the individual level rather than at the family level. Such measurements often obscure how mass incarceration affects children. From an anthropological perspective, examining incarceration's impact on children is important, as other adverse early life experiences as it not only affects individual's life histories but also those of their surrounding social networks [17, 18]. Understanding the impact of early life experiences on human development demands fundamental anthropological inquiry, for example into how both society and culture construct individuals over time. Understanding the impact of mass incarceration on women and children also is increasingly important from a drug use and addiction perspective [19-22]. Over the past few years there has been a growing recognition of the opioid epidemic in the US [23, 24]. Focus on drug use and addiction as a public health problem, instead of a deviant behavior should elucidate root causes which could ultimately lead to a decrease in the number of incarcerated individuals in the criminal justice system. Furthermore, a health focused approach, in which offending women receive treatment and probation instead of prison sentences, can potentially mitigate the negative effects of maternal incarceration. The aim of this paper is to examine how children are affected by maternal incarceration, and what factors protect or increase their risk for the negative effects of incarceration.

Georgia provides a valuable case study for female incarceration and its impacts on child development. According to the Georgia Department of Public Health, deaths related to drug overdose are now almost equivalent to those reported for motor vehicle accidents [25]. This increase in drug overdose deaths has left Georgia among the top 11 states in prescription drug overdose deaths [25]. Additionally, statistics on the prescription drug overdose upsurge across the state also illustrates that overdose deaths are rising among women [23]. Moreover, state-wide data on opioid addiction and overdoses have shown that the individuals at elevated risk are those that subsist among low-income populations, who reside in rural or urban areas. In addition, this population includes those who may have a record of mental illness and addiction to alcohol and/or drugs like cocaine or prescription pain medications [23]. The economic and health services resource divide between rural and urban populations leaves the majority of people living in rural communities with fewer employment opportunities and less access to adequate health care, particularly, drug treatment programs [25]. Therefore, many rural poor migrate to urban areas such as Atlanta with the hopes of improving their economic and health outcomes. Recent figures by the Brookings Institute have shown that Atlanta has consecutively held the top rank for the highest rate of income inequality in the US in recent years [26, 27] with increasing concentrations of people falling below the poverty line [28]. In such contexts, local prisons become safety nets for communities as they aim to separate themselves from the city's most vulnerable [19, 29].

A growing body of literature has demonstrated the extent to which drug addiction co-occurs with female incarceration [15, 30]; however, few studies have investigated the combined impact on child development [31-33]. This study examines effects of maternal incarceration on child development, among children of female inmates in the US criminal justice system. The intersection between incarceration and child behavioral health outcomes is particularly concerning as the US female prison population continues to increase [10]. Negative child behavioral health outcomes may be higher in this population as suggested by the substantial body of literature on maternal and child separation [34-39]. A large contributing factor to this lack of information may be the difficulty in conducting research within the prison system. As such, the effects of female incarceration on child development has been difficult to assess in part because few large-scale studies on the topic [40]. The current study uses data from a cross-sectional clinical sample of children from all over the State of Georgia who visit a clinic in Atlanta that provides care to children exposed to alcohol and drugs. These data were used to address the following hypotheses:

- Maternal incarceration leads to increases in internalizing and externalizing behavior problems in children.
- Among children of drug/alcohol using women, those who spend longer periods of consecutive time in their birth mother's custody report higher rates of internalizing and externalizing behavior problems
- Among children of drug/alcohol using women, those who spend longer periods of consecutive time in the custody of a non-maternal caregiver report lower rates internalizing and externalizing behavior problems.

Figure 1. Cycle of social environmental health disparities.

By examining the effects of maternal incarceration on child development, this paper intends to shed light on the causes of environmental health disparities amongst this population. Existing literature has demonstrated that children can be negatively impacted by their parent's incarceration in areas such as housing and schooling, all of which can lead to poverty and mental health problems [12-14]. Therefore, by examining the hypotheses, this paper aims to provide ideas of interventions that can be useful to researchers and policy-makers alike, as they attempt to decrease social-environmental health disparities in our communities.

OUR STUDY

Secondary data were collected for this study from a database maintained by the Emory Neurodevelopmental and Exposure Clinic (ENEC) in the Department of Psychiatry and Behavioral Science, Emory University School of Medicine. ENEC serves children with behavioral and developmental problems with known or suspected prenatal exposure to alcohol and drugs. All patients applying for diagnostic services at ENEC may agree to participate in this database for the purpose of research by signing an informed consent document. Data are abstracted from questionnaires and medical records. The clinic serves a diverse population from the State of Georgia and the Atlanta metropolitan area ranging in age from birth through adolescence. For the current pilot study, records of 40 preschool and school aged children were selected. Data collection took place between February and April 2017. Only children who had data on all the variables of interest were included.

Convenience sampling was used to select children whose mothers were incarcerated at the time of the clinic visit. Of the participants (20 case and 20 contrast), the case group

consisted of children who were separated from their mothers because of maternal incarceration. The contrast group consisted of children who were separated from their mothers at birth due to maternal drug use but not incarceration. The contrast group was chosen because it was demographically similar to the case group apart from incarceration (see Table 1). Individuals in both groups were selected because they were similar ages, shared similar prenatal exposures to drug and alcohol and were not in their birth mother's custody at the time of data collection. All data were first entered into a RedCap database and then transferred to Microsoft Excel for analysis. All participants provided consent as noted above and prior approval for the study was obtained from the Emory Institutional Review Board.

The variables of interest were defined and searches for children with relevant data were initiated with the key search terms including: jail, probation, arrest, prison, incarceration as well as foster care, birth mother, protective custody, after birth and Georgia Division of Family and Children Services (GDFCS) (a sub-division of the Health and Human services department that assists children in cases of child abuse or neglect) [41]. In addition to placing children in safe care, ideally with extended family members but predominately in foster or adoptive homes, GDFCS also provides financial assistance and psychological services to families in hopes of keeping children with their parents [41]. These search variables allowed us to find children that fit our study criteria.

Children in these searches who met both age and custody criteria were included in the final sample. For those children who did not qualify, the primary reasons for exclusion were age, paternal, not-maternal incarceration, lack of clarity on whether the children were in their birth mother's custody or in another form of placement. This initial search produced 100% of the contrast participants. However, it produced 75% of the case participants; thus, to collect the remaining 25% of the case participants, manual searches of children's records were conducted from the entire ENEC database which is comprised of approximately 600 children. Manual searches were conducted from the ENEC database because not all records were digitized into RedCap at the time of data collection. Data collection was completed following manual searches. Additionally, children whose caregivers had no knowledge of their background and biological family history were excluded from the study.

Quantitative Data Collection

Demographics: Basic demographic information (see Table 1) included age, race and sex. Age was determined through the question, "How old is the child?" Race was ascertained via the question, "What racial group does the child identify with?" Response options included "African American/black," "Asian/Asian American," "Caucasian/White," "Mixed Race/Other". Child sex was established via the question, "Is the child male or female?"

Child Behavior Checklist (CBCL): Internalizing and externalizing behaviors were examined by reference to the results of the Child Behavior Checklist (CBCL) that had been administered to all children receiving clinical services at ENEC. This widely used 113-item questionnaire assesses behavioral problems in children [42]. A reliable and well-validated instrument, the CBCL's targeted symptoms include aggression behavior, anxious/depressed, attention problems, rule-breaking behavior, somatic complaints, thought problems, withdrawal/depressed and social problems [42]. Child behaviors were classified as either internalizing or externalizing to be consistent with the study hypothesis. Internalizing

behaviors are seen as behaviors through which children may focus their thoughts, feelings and emotions inwardly [43]. These include “fear of trying new things, avoiding looking at others in the eye, and a lack of concentration” [42]. On the other hand, children who exhibit externalizing behaviors, are those who focus their thoughts, feelings and emotions in an outward way [44]. These include being “cruel to animals, defiant, and oppositional behavior, and demands that their needs be met immediately” [42]. Respondents were asked to consider the presence of each item/symptom over the child’s life and to rate each item along a Likert scale from 0 (never true) to 2 (very true or often true). Possible CBCL scores range from 50 to 100. CBCL scores are T-Scores meaning the mean of 50 for the population and a standard deviation of 10. Scores greater than 70 are considered clinically significant, however, scores 60 to 69 are possibly ‘borderline’ [45]. As such, the CBCL does not report scores less than 50 as these are not considered to be meaningful in terms of identifying behavior problems. This article therefore presents CBCL scores of ≥ 60 as these scores are indicative of internalizing/externalizing problems [45].

Quantitative Variables

In addition to maternal incarceration, this study also investigated the effects of time in current caregiver’s care and time in birth mother’s care. These two variables were chosen in an effort to understand whether stable caregiving following separation from the birth mother had the potential to decrease negative child behavioral health outcomes. Additionally, time in birth mother’s care was selected as a variable of interest in order to understand whether separation from birth mother after living in her custody for longer periods increased negative behavior health outcomes. These two variables were also chosen because the case group had spent time in their birth mother’s custody, while the contrast group had not. This was done in order to understand whether the case group would exhibit negative behavioral health outcomes due to this separation. Additionally, this variable was selected because living with a drug using mother can also be a stressor for children. Thus, separation due to incarceration could potentially yield positive results.

Table 1. Participant demographics: Case and contrast

Characteristic	Case				Contrast	
Sex	Male (n = 12)	Female (n = 8)	Total (n = 20)	Male (n = 13)	Female (n = 7)	Total (n = 20)
Age	Mean = 5 years, 6 months	Mean = 5 years, 1 month	Mean = 5 years, 3 months	Mean = 5 years, 5 months	Mean = 6 years, 4 months	Mean = 5 years, 9 months
Race						
Black	3	5	8	2	4	6
White	6	3	9	8	1	9
Mixed Race	3	0	3	2	2	4
Asian	0	0	0	1	0	1

Qualitative Data Collection

The qualitative data presented in this article come from clinical records of children's biological family histories. These records were collected from children's caregivers at the time of the child's clinic visit. Major themes in these interviews revolved around child's relationship with birth parents, reasons for separation from birth parents, and birth parent's childhood, educational history, and birth parent's criminal records. These reports served as semi-structured interviews because they were nested within children's clinical evaluations in which caregivers were given prompts and in return they gave detailed open-ended responses. Family and social histories not only provided information not only on the child's background but also provided information on the birth mother's background as birth mother's life histories were included in these documents. The depth and breadth of these histories differed due to a caregiver's knowledge of a child's background. Some caregivers were relatives or had been given detailed case histories by children's case managers. As a result, they were able to provide detailed information on the child's background.

Data Analysis

The analytic approach undertaken aimed to determine whether maternal incarceration influences CBCL scores; that is, whether the case group reported higher CBCL scores than the contrast group. Univariate tests (t-tests) were used to statistically assess whether differences would be observed between the two groups. A multivariate logistic regression was used to estimate the effects of maternal incarceration and the other covariates on internalizing and externalizing CBCL scores. Statistical analyses were performed using the software program, Microsoft Excel.

Qualitative interviews were de-identified and exported into MAXQDA (a qualitative data analysis software program). In MAXQDA, content analysis was used to identify discussions around separation from birth mother, incarceration, and child behavior. Initially, five cases and five contrast participants were coded. This was done in order to create a codebook. The codebooks were comprised of recurrent codes that were appearing in the respective interviews. Following the creation of the codebook, the remaining documents were coded, only rarely adding new codes. Examples of these key codes included mentions of maternal incarceration, reasons for incarceration, mentions of child abuse, maternal background, and descriptions of the child's behavior. These codes led to three thematic sections. The first theme emerged around maternal incarceration and reasons for maternal incarceration. The second theme consisted of topics discussing maternal childhood and personal history. The final theme was comprised of topics related to descriptions of the child's behavior.

RESULTS

There were no significant differences in demographics. Case and contrast groups were evenly matched as children were comprised of similar age, sex and race categories.

T-Tests

Both case and contrast groups had similar CBCL scores. The mean CBCL score for internalizing behavior for case participants was 59.0 and the mean CBCL score for internalizing behavior for contrast participants was 58.95. Both case and contrast groups were therefore higher than the normative mean CBCL score which is 50. However, these scores were both less than 60, meaning they are not indicative of a clinical level of internalizing behavior problems. Alternatively, the mean CBCL score for externalizing behavior for case participants was 63.47 and the mean CBCL score for externalizing behavior for contrast participants was 63.35. Both case and contrast scores were significantly higher than the normative mean CBCL score of 50. They were also above 60 meaning the total externalizing scores of case and contrast participants were indicative of externalizing behavior problems.

Table 2. Case and contrast internalizing and externalizing CBCL scores

	Case Mean	Contrast Mean	Mean diff	5%	95%	t	df	p
Internalizing Scores	59.00	58.95	0.050	-8.296	8.396	0.01201	36.01	0.9904
Externalizing Scores	63.47	63.35	0.124	-8.984	9.232	0.028	35.74	0.9782

Multivariate Regression Analysis

Multivariate regressions were used to examine other factors that might be affecting the CBCL scores.

In addition to maternal incarceration, the other variables considered for this model were: time spent with birth mother and time spent with current caregiver. In this analysis neither of these variables influenced internalizing behavior significantly. The p-value for time spent with current caregiver was 0.247; for time spent with birth mother was 0.181 and for maternal incarceration was 0.327. None of these p-values are statistically significant, therefore the proposed hypotheses were not supported. The R-squared statistic demonstrated that the model only explained 5% of the variance in internalizing behavior scores. Thus, other etiological variables are influencing internalizing behavior; however, these were not accounted for in this model.

Table 3. Internalizing behavior multivariate scores

Variable	Coefficient	p-value
Time with current Caregiver (months)	-0.074	0.247
Time with Birth Mother (months)	-2.229	0.181
Maternal Incarceration	3.298	0.327
Intercept	63.53	3.55e-12
R-squared	0.05	

In this analysis as well, none of the independent variables had a statistically significant influence on externalizing behavior. The p-value for time spent with current caregiver was 0.396; for time spent with birth mother was 0.113; for maternal incarceration was 0.141. None of these p-values are statistically significant, therefore my model did not support the proposed hypotheses. R-squared demonstrated that the model only explained 8% of the variance in externalizing behavior scores. Therefore, as with internalizing behavior, other unknown factors not accounted for in this model are influencing externalizing behavior.

Table 4. Externalizing behavior multivariate scores

Variable	Coefficient	p-value
Time with current Caregiver (months)	0.002	0.396
Time with Birth Mother (months)	-3.131	0.113
Maternal Incarceration	8.473	0.141
Intercept	62.99	5.35e-11
R-squared	0.08	

Qualitative Results

Although the T-test results illustrated that both case and contrast participants report higher than normal internalizing and externalizing CBCL scores, the regression model suggested that factors other than those in the model affected CBCL scores. A subsequent examination of children's family and social histories was attempted to better understand the factors that could be affecting these results. The family and social histories of these children revealed some of the other factors that might be influencing these high CBCL scores.

These family and social histories illustrated that there is more to these women than incarceration. The biological mother's life histories revealed childhood trauma, sexual and physical abuse, poverty, and limited education. Mothers reported 8th or 9th grade education and most significantly, adolescent alcohol and drug use, which continued throughout their lives and pregnancies. Two excerpts from birth mothers' life histories reflect these points:

Her biological mother initiated substance use as young as 11 years of age when she began smoking. Her mother reportedly had her first child at 14 and was forcibly raped before she was 16 years of age. She reportedly quit school during the 9th grade as a result of her 1st pregnancy. She also had a long history of stays with the juvenile justice program in her youth. (Case, B32: Names are changed to preserve anonymity)

Ben was born to Quinn McBerry, who was 20 years old at the time of Ben's birth. Ms. McBerry completed the 8th grade. Per reports, Ms. McBerry drank alcohol while pregnant, with a pattern of binge-drinking on weekends, and was also using marijuana, methamphetamine, and tobacco during the pregnancy. (Contrast, F15: Names are changed to preserve anonymity)

These family histories are illustrative of both case and contrast maternal life histories. They demonstrate that both groups of mothers experienced early life trauma and have been abusing substances since they were younger. Additionally, both mothers in these groups have limited education as their highest level of education is 9th and 8th grade, respectively. These two examples serve to suggest that these two groups have similar life histories, which could be a contributing factor as to the lack of differences between case and contrast groups.

These family and social histories also revealed that the lives of these children prior to maternal incarceration contained information pertaining to drug and alcohol abuse, neglect, housing instability and poverty.

Excerpts from children's lives with their birth mothers also reveal similarities:

The Department of Children and Family Services removed her from her biological mother as a result of neglect, substance abuse, unstable housing and unemployment, a previous removal of her other two children, and incarceration related to a probation violation for a shop-lifting conviction." (Case, B32: Names are changed to preserve anonymity)

Jeremy was taken into the Brown home immediately from the neonatal nursery and has never lived elsewhere. His biological mother had a history of substance abuse and social and legal problems." (Contrast, F15. Names are changed to preserve anonymity)

These family histories illustrate that although the contrast participant was adopted at birth, he was pre-exposed to his mother's negative environment in utero. Additionally, the case participant's life history also suggests exposure to negative early life events as his mother's incarceration for shoplifting coincided with other charges such as child neglect, unstable housing and substance abuse, all of which are detrimental to child development. These accounts suggest that maternal incarceration is an additive not definitive factor in the children's behavioral health outcomes.

DISCUSSION

Anthropologists have long focused on child development, maternal and child relationships and psychosocial stress in efforts to understand the biological and sociocultural underpinnings of development [46-50]. As such, anthropological research has provided evidence for the ways through which biological and psychosocial early-life stress can influence adult health and disease outcomes [17, 48, 51].

As prior research has suggested, maternal incarceration as an early-life stressor can have long-term consequences that affect children well into adulthood [16, 40]. Evidence has demonstrated that children of incarcerated women are themselves likely to abuse drugs, develop mental health problems and be incarcerated later in life [16, 40]. These effects illustrate that maternal incarceration may have influences that extend beyond the individual child, but can potentially influence subsequent generations, thereby reproducing the cycle of incarceration. Furthermore, the transgenerational effects of maternal incarceration could lead to similar health and social effects as those experienced by individuals living in poverty [17]. In continuation of this investigative tradition, this study aimed to examine the impact of maternal incarceration as a psychosocial stressor on child development. However, this study did not demonstrate statistically significant results regarding the effects of maternal incarceration on children's behavioral health outcomes when a contrast group with similar demographic characteristics was used. However, the t-tests illustrated that both case and contrast participants report higher than normal -'borderline' clinical internalizing and externalizing CBCL scores. Although the internalizing score for either group were not indicative of problems, the externalizing scores for both groups were elevated. Therefore,

although these groups exhibit results that suggest clinical problems, we cannot conclude that maternal incarceration itself had any additional effects.

Figure 2. Breaking the cycle of social environmental health disparities.

A large contributing factor to the similarities in these results is that both groups of children have experienced stressful conditions. Both groups have experienced disruptive childhoods as they have been separated from their biological mothers and have also been prenatally exposed to drugs and/or alcohol. Most significantly, the mothers of these children also experienced traumatic childhoods and subsequently continued these patterns of abuse and neglect with their own children.

The qualitative results suggest that psychosocial stressors such as child neglect, drug addiction, poor education and poverty contribute to negative CBCL scores for children. Additionally, these qualitative results illustrate that it can be difficult to isolate a single psychosocial stressor as the independent cause of negative child behavioral outcomes as they overlap and co-occur [18]. Maternal incarceration in this case occurred in the presence of child neglect, poverty, limited education and substance use. The qualitative results therefore suggest that in living with mothers and/or simply being prenatally exposed to their birth mother's negative environments such as maternal drug use, these children were already at risk of negative child behavior outcomes regardless of maternal incarceration. Therefore, to better understand the causes of negative CBCL scores, it is important to not only examine maternal incarceration or the variables included in the regression, but to also examine the social environments that these children were exposed to while in their birth mother's custody.

Study Limitations

The biggest limitation of the study was the sample size. This total sample of 40 participants may have been underpowered and therefore too small to yield any statistically significant results. Thus, the small sample size may erroneously suggest that incarceration is not a factor in child behavior (as suggested by the observed trends). Follow up studies with larger sample sizes are needed to determine the effects of maternal incarceration on child behavioral health outcomes. Another limitation of this study is that the sample is a self-selected clinical sample, meaning that the children in this sample were individuals whose caregivers knew about their possible prenatal exposure to alcohol and/or drugs and chose to bring them in for an evaluation at ENEC. These children are therefore not representative of the general population and may have been more likely to have behavior problems.

CONCLUSION

Despite these limitations, this study provides a starting point for efforts to understand the effects of maternal incarceration on children's behavioral health outcomes. The qualitative data were able to elucidate some of the challenges in studying this population. The qualitative data demonstrated that the point of examination or intervention for negative child behavioral health outcomes is not when mothers are incarcerated but before, as the factors that lead to both maternal incarceration and unfavorable CBCL scores occur when children are in their mother's custody. Because the contrast participants were comprised of children who also experienced disruptive childhoods, they served as an important comparison as they showed similar CBCL scores. The contrast group therefore suggested that the behavioral problems experienced by this clinical population may occur before incarceration.

This study was also able to produce valuable information on breaking the cycle of poverty. It demonstrated that although maternal incarceration is a stressor in children's lives, the points of intervention are before mothers are incarcerated. The qualitative data revealed how these women's lives developed from their limited education to their adolescent and early adult drug use and their subsequent incarceration and loss of child custody are emblematic of their social environments. The two main points of intervention when attempting to break the cycle of poverty are early education and drug treatment. Early education will break the cycle as by keeping children in school they are more likely to be exposed to positive influences, not engage in drug use, and instead of being on a path to incarceration, they can find employment and be productive members of society. Drug treatment can help mitigate some of the negative effects of drug use on child development as the qualitative data illustrated that maternal substance abuse was one of the main reasons as to why children were removed from their birth mother's custodies. Additionally, providing women with drug treatment can decrease the number of those incarcerated as health focused approaches attempt to keep families together. As US maternal incarceration rates continue to rise, the question of what leads to maternal incarceration will remain salient, as will that of its impact on children. It is therefore crucial for researchers and policy-makers alike to implement supportive interventions that are aimed at breaking the cycles of poverty and incarceration before more women are incarcerated.

ABSTRACT

Housing instability is thought to be a major influence on children's healthy growth and development. However, little is known about the factors that influence housing instability, limiting the identification of effective interventions. The goals of this chapter were to 1) explore factors, including material hardship, satisfaction with living conditions and housing disrepair, that predict housing instability (total number of moves that a child experienced in the first seven years of life); and 2) examine the relationship between housing instability and child behavior at age 7 years, measured by the Child Behavior Checklist. We analyzed these associations among children enrolled in the Columbia Center for Children's Environmental Health (CCCEH) Mothers and Newborns study. In our analysis, we found that housing disrepair predicted residential change after three

* Corresponding Author's Email: jh2678@cumc.columbia.edu.

years of age, but not before. Persistent material hardship over the seven-year time period from pregnancy through age 7 years was associated with increased number of moves. Children who experienced more than three moves had significantly more thought- and attention-related problems compared to children who experienced fewer than three moves over the same time period. Children who experienced more than three moves also had higher total and internalizing problem behavior scores, although these differences were not statistically significant. We conclude that housing instability is associated with problem behavior related to thought and attention in early childhood and that interventions to reduce socioeconomic strain may have the greatest impact in breaking the cycle of children's environmental health disparities related to housing instability.

INTRODUCTION

Housing instability is a growing problem in the United States, particularly for those living in urban, low-income neighborhoods [1, 2]. Despite the importance of stable housing, current research has struggled to define and identify housing instability and its effects on children's health. Previous studies have used different parameters to measure housing instability, including frequent moves and living with relatives and friends [4-6] and the US Department of Health and Human Services has defined housing instability using housing cost, housing quality, neighborhood stability, crowding, and homelessness [3].

Recent research has begun to focus on the impact of housing instability, in its many forms, on child health and development [1]. It is hypothesized that young children are at greater risk of adverse effects of living environments, as this time period serves as a critical window for establishing socialization and learning habits [7, 8]. Additionally, the effects of housing instability may be compounded when combined with other challenges faced by low-income families, such as lack of resources [1]. Previous studies have found that housing instability is associated with deficits in overall academic achievement [9], emotional regulation [7, 8], and verbal abilities [10]. These health outcomes can have serious long-term effects as children progress through adolescence and adulthood, including decreased educational attainment [11], increased participation in risky behaviors [12, 13], and a greater risk of adult-onset chronic diseases [14].

In the present paper, we explore the predictors of housing instability, including physical characteristics of housing and measures of socioeconomic strain in a low-income urban population of minority mothers and children. We also evaluate how housing instability, characterized by frequency of residential moves, affects child behavior assessed at age 7 years. We expect these results will inform future public health programs focused on identifying appropriate intervention points at which to break the cycle between unstable housing and child health outcomes.

OUR STUDY

The Mothers and Newborns Study is a longitudinal birth cohort maintained by the Columbia Center for Children's Environmental Health (CCCEH). The study enrolled 727 pregnant women living in Northern Manhattan and the South Bronx between 1998 and 2006.

Study participants were African American or Dominican and were between the ages of 18 and 35 years at the time of recruitment. Subjects were excluded from the cohort if they reported smoking cigarettes or using other tobacco products during pregnancy, used illicit drugs, had their first prenatal visit after the 20th week of pregnancy, or had one of the following pre-existing conditions: diabetes, hypertension, or known HIV infection. Cohort participants were excluded from the current analysis if they did not have complete information on residential history at the prenatal and ages 1, 2, 3, 5 and 7-year follow up visits or if the mother was not administered the Child Behavior Checklist (CBCL) at the 7-year visit (see Figure 1). All study protocols were approved by the Institutional Review Board of Columbia University. Before each visit, mothers were informed about all study procedures and provided written informed consent to participate.

Mothers and their children were followed up at approximately 1, 2, 3, 5 and 7 years after birth. Research workers conducted a structured interview to ascertain demographic characteristics of the mother (i.e., age at delivery, ethnicity, education, relationship status) and child (i.e., gender). Maternal demoralization, defined as the extent to which a mother experiences nonspecific psychological distress, was additionally assessed at each study visit using the Psychiatric Epidemiology Research Instrument- Demoralization (PERI-D) scale [15].

Figure 1. Final data analysis sample.

Residential History, Building Disrepair and Housing Satisfaction

At each study visit research assistants recorded all addresses at which the mother-child pair resided since the previous study visit. We summed the number of study visits for which an address change occurred since previous study visit to create an index of instability experienced by each child. We defined unstable housing as a greater than 3 moves from the prenatal period to age 7 years. Research workers also collected information on maternal-report of paint chips or dust, holes in the ceiling or walls, mold, and leaky pipes in their current residence. We coded these building disrepair variables as 1 or 0 based on whether they were present or not. Similarly, pest variables, including maternal report of roaches, rodents, and other insects were also recorded and coded as 1 or 0 based on their presence. At

each time point, we summed the number of building disrepair and pest items to create a visit-specific measure of housing disrepair (range: 0 to 7), which we subsequently categorized into three levels: no housing disrepair, one housing disrepair item, or two or more housing disrepair items. Finally, mothers rated their level of satisfaction with their current living conditions on a scale of one to five (one indicating “very satisfied” and five indicating “very dissatisfied”) at each interview. We created a dichotomous variable by collapsing “very satisfied,” “somewhat satisfied,” or “neither satisfied nor dissatisfied” into one level and “very dissatisfied” or “somewhat dissatisfied” responses into a second level.

Material Hardship

At each study visit mothers were asked a series of questions adapted from a survey designed to measure material hardship among urban populations [16] to determine the level of economic strain that they were experiencing. This included questions about the mother’s self-reported ability to afford housing/rent, gas and/or electricity, food, and clothing. We summed the number of ‘hardships’ at each time point to create a material hardship scale ranging from 0 to 4. As previously described [17], we used Latent Class Growth Analysis to empirically estimate trajectories of material hardship from pregnancy through age 7 years. We found that mothers belonged to one of four hardship trajectories: increasing over time, decreasing over time, persistent low, and persistent high. Given our interest in socioeconomic strain, in all analyses we compared the persistent high hardship trajectory to the other three trajectories (low or fluctuating hardship) collapsed into a single group.

Child Behavior

At the seven-year follow-up visit, mothers were administered the Child Behavior Checklist (CBCL), which is a validated tool for assessing behavior problems in children [18]. Mothers rated their children’s behavior on 113 items as never present, sometimes present, or often present. Scores on these items are summed and grouped into syndrome scales, which provide information across several behavioral domains. We analyzed the scores from several scales, including: attention and rule breaking (collectively: externalizing behaviors), anxiety/depression, withdrawn, and somatic complaint (collectively: internalizing behaviors), and attention, thought, and social problems. A total behavioral problem score is obtained from the sum of all eight syndrome scores.

Data Analysis

To better understand the predictors of housing instability, we examined the relationship between housing disrepair, maternal satisfaction with housing, and housing instability (see Figure 2). We analyzed the relationship between housing disrepair and maternal satisfaction with living conditions at each time point using a logistic regression. Satisfaction with living

conditions and housing disrepair at each time point was analyzed as a predictor of having moved by the time of the next interview.

Figure 2. Conceptual diagram of predictors and outcomes of housing instability.

We assessed CBCL outcomes using the raw scores from the checklist in a negative binomial regression model, which is better suited for this type of count data and has been used in previous studies with the CBCL [19]. The number of moves over 7 years was treated as a categorical predictor of CBCL scores using the following groups: 0-1 moves, 2-3 moves, and more than 3 moves. Since the CBCL is a maternally-reported questionnaire, and responses may be affected by the mother's psychosocial well-being, we included maternal demoralization score, or the extent to which a mother experiences nonspecific psychological distress, in our final model [15]. Additional covariates included in the model were maternal education, child age, child gender, and child ethnicity, based on their prior association with child behavior [19].

We also examined the role of material hardship in the main analysis, since material hardship has previously been shown to predict behavior problems in childhood (see Figure 2) [11]. In order to understand how long-term hardship was related to housing instability, total material hardship over the seven years was analyzed using a latent variable model, which categorized each participant into one of four categories: increasing hardship over time, decreasing hardship over time, consistently low hardship, and consistently high hardship [17]. In our final model for this analysis, we analyzed the total number of moves over the seven-year time period as a mediator in the relationship between material hardship and housing instability.

OUR RESULTS

The final sample for this analysis included 496 subjects of the original 727 subject cohort. As illustrated by Table 1, the study population was completely of Dominican or African American ethnicity. These demographic characteristics were not significantly different between the participants included ($N=496$) and those excluded ($N=231$) due to missing residential history or CBCL scores. The average age of the mother at the prenatal visit was approximately 25 (25.2 ± 4.96) years old and approximately three-quarters (74.2%) of the mothers were single. Almost one quarter (21.4%) of the study population experienced persistent high material hardship throughout the study period.

Housing Disrepair, Satisfaction with Living Conditions and Housing Instability

We assessed the relationships between housing disrepair, satisfaction with living conditions, and housing instability using Pearson's chi-squared tests. Higher housing disrepair scores at each time point after birth were associated with lower maternal report of satisfaction with living conditions at the same time point (see Table 2). However, dissatisfaction with living conditions did not always predict movement at the following interview. We did observe a difference in the probability of a change in housing in families with older versus younger children. Although this was not the case for children under three years, there was a statistically significant positive association between at least one address change and housing disrepair at the 3-year visit (OR=1.81, $p<0.05$) and 5-year visit (OR=1.67, $p<0.05$) (see Table 2).

Table 1. Characteristics of maternal-child pairs included in the analysis (N=496)

	N (%) or Mean±SD
Maternal age at prenatal visit	25.2 ± 4.96
African American	188 (38.0)
Dominican	307 (62.0)
<HS education at prenatal visit	178 (32.2)
Married or stable relationship at prenatal visit	128 (25.8)
Maternal demoralization at 7 year visit	0.97 ± 0.68
Male	229 (46.2)
Child age at Child Behavior Checklist	7.06 ± 0.20
Persistent high material hardship	106 (21.4)
Maternal dissatisfaction with living conditions:	
Prenatal visit	49 (9.88)
1 year visit	57 (11.5)
2 year visit	70 (14.1)
3 year visit	62 (12.5)
5 year visit	62 (12.5)
7 year visit	64 (12.9)
Ever move since previous study visit:	
1 year visit	80 (16.1)
2 year visit	84 (16.9)
3 year visit	104 (20.9)
5 year visit	146 (29.4)
7 year visit	145 (29.2)
Total number of study visits between which a residential move occurred:	
0-1	301 (60.6)
2-3	173 (34.8)
>3	22 (4.44)
≥2 building disrepair items	
Prenatal visit	379 (76.4)
1 year visit	324 (65.3)
2 year visit	320 (64.5)
3 year visit	302 (60.8)
5 year visit	285 (57.4)
7 year visit	272 (54.8)

Housing Instability and Child Behavior

The relationship between housing instability and child behavior was examined using a negative binomial regression model that controlled for material hardship, maternal demoralization, maternal education, child age, child gender, and child ethnicity. In the adjusted model, we found that children who experienced housing instability, defined as a residential move at more than three study visits (N=22, 4.44%), had 1.95 ($p<0.05$) and 1.56 ($p<0.05$) times the odds of thought-related and attention-related problems compared to children with stable housing (defined as a residential move between 1 or fewer study visits), respectively. The total number of behavior problems and overall internalizing problems were also higher in children who experienced more than three moves over seven years, but these associations were not statistically significant after adjusting for confounders (see Table 3).

Table 2. Association between housing disrepair, satisfaction with living conditions, and residential moves

	Dissatisfied vs. satisfied with living conditions OR (p-value)	Ever vs. never move since previous study visit OR (p-value)
Housing disrepair: ≥ 2 items vs. 0 items		
Prenatal	0.812 (0.544)	N/A
1 year	2.12 (0.023)	0.842 (0.541)
2 year	2.16 (0.009)	1.40 (0.198)
3 year	2.42 (0.005)	0.895 (0.629)
5 year	2.21 (0.008)	1.81 (0.005)
7 year	3.07 (0.000)	1.67 (0.012)
Dissatisfied vs. satisfied with living conditions		
Prenatal	N/A	N/A
1 year	N/A	0.687 (0.416)
2 year	N/A	1.07 (0.856)
3 year	N/A	1.32 (0.372)
5 year	N/A	3.26 (0.000)
7 year	N/A	0.913 (0.767)

Table 3. Summary of CBCL results in relation to housing instability and persistent material hardship included in the same model^a

CBCL Syndrome	Housing instability ^{b, c} IRR (p-value)	Persistent hardship ^d IRR (p-value)
Anxiety/Depression	1.24 (0.32)	1.27 (0.04)
Withdrawn	1.46 (0.20)	1.34 (0.05)
Somatic complaints	1.10 (0.72)	1.40 (0.01)
Social problems	1.37 (0.13)	1.13 (0.26)
Thought problems	1.95 (0.02)	1.56 (0.01)
Attention problems	1.58 (0.04)	1.27 (0.05)
Rule breaking behavior	1.27 (0.29)	1.15 (0.24)
Aggressive behavior	0.00 (0.99)	1.19 (0.14)
Internalizing behavior problems	1.25 (0.25)	1.33 (0.01)
Externalizing behavior problems	1.08 (0.71)	1.18 (0.13)
Total behavior problems	1.29 (0.15)	1.23 (0.03)

Abbreviations: CBCL- Child Behavior Checklist

^a Models also adjusted for maternal demoralization, maternal education, child gender, child ethnicity, and child age at time of CBCL.

^b Defined as more than 3 residential moves from the prenatal period to age 7 years.

^c Reference group defined as 0-1 moves over the first 7 years.

^d Reference group defined as to low or fluctuating hardship.

The Role of Material Hardship

Compared to families with low or fluctuating material hardship, we found that families experiencing persistent high material hardship were significantly more likely to experience housing instability (Incidence Rate Ratio (IRR)=1.36, $p<0.05$). Additionally, children in families who experienced persistent material hardship had significantly higher internalizing (IRR=1.32, $p<0.05$) and total (IRR=1.22, $p<0.05$) problem scores as well as significantly higher anxiety/depression (IRR=1.25, $p<0.05$), somatic complaint (IRR=1.41, $p<0.05$) and thought-related (IRR=1.53, $p<0.05$) problem scores. When we adjusted for the number of moves a child experienced, the effect of persistent material hardship on anxiety/depression, somatic complaint, thought-related, internalizing, and total problems was virtually unchanged. The results for all syndrome scores from the adjusted model are presented in Table 3.

DISCUSSION

We examined the predictors of housing instability, as well as behavioral outcomes of housing instability among a subset of participants enrolled in the CCCEH Mothers and Newborns birth cohort. We observed significant inverse associations between housing instability and child behavior at age 7 years. Material hardship over time was a significant predictor of poor behavior outcomes, and was also associated with housing instability. Housing disrepair was associated with an address change at 3 and 5 years of age, indicating that housing disrepair may predict housing instability as children grow older.

Figure 3. Breaking the cycle of environmental health disparities related to housing instability and child behavior.

These findings demonstrate the importance of material hardship as a predictor of housing instability as well as an independent predictor of child behavior outcomes. While building disrepair had some effect on movement, it was only a significant predictor in the later years of early childhood. We found that both attention- and thought-related behavior problems were

associated with housing instability, even when controlling for material hardship. Problems with attention may include concentration difficulties, impulsivity, day dreaming, difficulty sitting still, nervousness, and poor performance in school [18]. Thought-related problems may include seeing or hearing things, repeating acts, and having strange ideas and behaviors [18]. These are issues that can have serious consequences for children, especially in terms of their academic performance and social and emotional well-being [7, 8, 11]. These results are consistent with those from the Fragile Families and Child Wellbeing Study, which saw increased attention problems in children who experienced both housing instability and poverty [11].

The results from this analysis indicate that economic strain may be an optimal point of intervention in order to both reduce frequent moves and decrease the effects of housing instability on child neurobehavioral development (see Figure 3). Previous research shows that families who receive subsidies or energy assistance are less likely to experience frequent moves [20]. However, families eligible for housing subsidies rarely receive them due to the high demand and low availability, especially in large urban areas [21]. There is a clear need for greater financial support for low-income families experiencing material hardship, but recent investment has instead addressed the issue with new structural development and improvement. These efforts to improve neighborhoods and living conditions often backfire on the immediate community, leading to increased cost of living, higher property taxes, and eventual gentrification [22]. Other housing programs, such as the Moving to Opportunity for Fair Housing initiative (MTO), focus on increasing a family's upward mobility rather than stability [23]. This analysis suggests that financial capital may be better spent on programs that increase a family's ability to remain in a long-term home, particularly for those living in urban neighborhoods.

Study Limitations

There are several limitations to our analysis. We did not have information on why the mothers in the study cohort moved, so we cannot determine if the move was forced or a choice. Additionally, it was not feasible to determine whether a move was lateral, downwards, or upwards in terms of living conditions or neighborhood indicators of poverty, based on the available measures. Our exclusion parameters prevented subjects with incomplete address data, likely due to loss to follow up or inability to locate, from being included in the analysis. These mothers may have experienced high levels of housing instability, introduced selection bias and prevented us from evaluating the full impact of housing instability in this cohort. The CBCL, which was used to measure child behavior, was completed by the mother rather than direct observation of the child, which introduces reporting bias. However, we included maternal demoralization to lessen this bias. This analysis was done in a cohort of low-income, urban, minority mothers, and the results may not be reproducible in other highly mobile families, such as migrant workers or military families. Despite these limitations, our analysis included detailed and thorough information on housing characteristics and material hardship. These parameters were collected at several time points throughout the study period, allowing us to understand the longitudinal effects of possible predictors of housing instability.

CONCLUSION

Material hardship is a predictor of behavior problems in childhood and is also significantly associated with housing instability. Housing instability is associated with increased behavior problems in childhood, particularly in relation to thought- and attention-related processes. These results support the idea that housing assistance in the form of subsidies may be the most effective use of spending to combat the issue of housing instability for families living in low-income neighborhoods.

Chapter 261

DDT EXPOSURE, SOCIO-ECONOMIC STATUS AND NEURODEVELOPMENTAL OUTCOMES IN CHILDREN

ABSTRACT

Owing to high malaria burden, the Government of the Republic of Zambia is implementing an Integrated Vector Control Program. This encompasses Indoor Residual Spraying using Dichlorodiphenyltrichloroethane (DDT), and other chemicals. DDT, a persistent organic pollutant, is banned in the developed world, due to its toxic effects on the environmental and human health. Despite the country using DDT in the last 15 years, there have been no corresponding studies to establish whether it has any effects on human health. This study focused on studying the association of recent exposures on the neurodevelopmental outcomes of children in selected locations. Further, we evaluated the role other factors contributed to the outcomes. We conducted a survey targeting mother and child pairs in the Chawama and Mongu townships of Zambia. Utilizing the Ages and Stages Questionnaire (ASQ), we assessed children's abilities in communication, gross motor, fine motor, problem solving, and personal social interaction domains. We also collected information about maternal characteristics. Our results revealed median neurodevelopmental scores within the range that warranted further attention. Age seemed to modify the effect of chemical exposure on fine motor and personal social domains. Generalized linear models showed the strongest predictors of the children's neurodevelopment were mother's marital status, role in the family, income levels, and type of house. The area of chemical application was a significant factor. These results call for increased investment in improving the socio-economic status of communities and women in particular. This will enable them provide a more nurturing and stimulating environment for their children.

INTRODUCTION

A child's physical and social environment plays a key role in their development and health. Because of poverty and other limiting socio-economic factors that remain a challenge in many countries, an infant's neurodevelopment may be compromised by a host of influences ranging from genetics to socio-cultural factors [1]. Environmental factors, including chemicals such as lead, mercury and persistent organic pollutants (POPs), are principally detrimental during prenatal and early child development of the brain. These are largely dose and time dependent, and can affect the same developmental process differently depending on its particular vulnerability at that point in time [2]. Dichlorodiphenyl-trichloroethane (DDT) is one of the chemicals in the class of POPs that are still present in Zambia, despite its being banned in the developed world. It has, in the last 15 years, been used for malaria control as an indoor residual spraying (IRS) insecticide, owing to its long lasting effect and relatively cheaper cost when compared to other chemical alternatives [3].

Figure 1. Cycle of environmental health disparities.

There are other factors that determine human infant development, which when combined with exposure to chemicals such as DDT, may predispose a child to adverse health risk factors and neurodevelopmental outcomes. These are grouped into four main categories: socio-economic, residential options and characteristics, environmental impacts, and other compounding factors as presented in Figure 1 [4]. All these factors have to be considered together when studying infant neurodevelopment, as they may lead to effects which are more pronounced when combined in a single individual [5-9]. These disturbances to the brain during prenatal development have been shown to cause a wide range of outcomes in later years ranging from clinical ones such as dyslexia, epilepsy and schizophrenia to antisocial behaviors such as substance abuse and criminality [2].

Worldwide, several epidemiological studies have been conducted on effects of DDT on health outcomes, such as reproductive indicators, neurological symptoms and other associated impacts [10-27]. However, these have been on previously exposed communities or occupationally exposed individuals.

In Africa, some countries are still using DDT for malaria control. Studies have been carried out in South Africa, Botswana, and Mozambique to map DDT exposure in various environmental media such as soil, water and fish [28-30]. In terms of human matrices, studies have been conducted in South Africa on concentrations in breast milk and blood serum [29]. Important to note is that the only studies that have been undertaken looking at an association between exposure and a health outcome have been in South Africa, with the study population drawn from former male spray operators and residentially exposed males with specific focus on male reproductive health [31, 32].

Children in already marginalized populations are more likely to be impacted by DDT as this pesticide is applied only to rough, un-plastered surfaces often housing economically disadvantaged people. Children are highly vulnerable to chemicals, due to their unique characteristics. They play on polluted grounds and surfaces, have hand-to-mouth behavior, and usually follow a specific set-out diet. The persistence of IRS chemicals on environmental media, such as soil and water in addition to household items like furniture, beddings and other absorbent surfaces, places children at the highest risk of exposure. Additionally, children have decreased abilities to detoxify and excrete some chemicals, potentially impairing their rapid growth and development of their vital organ systems [33].

Given the HIV pandemic and the incidence of poverty in Zambia, it is highly likely that these effects will be more pronounced in the Zambian population. Cumulatively, a massive 246,000 kg of DDT have been brought into the country since 2000 and applied in people's homes. However, no studies have been carried out in Zambia to ascertain the fate of these chemicals in the environment and the impact on human health, despite the emphasis placed by the Stockholm Convention on the need to monitor the use and the impact on human health arising out of the use of DDT. This study therefore aimed to establish the prevalence of DDT in selected communities of Zambia and assess the neurodevelopment outcomes in children within these communities. It further evaluated the influence of socio-economic and environmental factors on the observed outcomes. This paper presents results from the neurodevelopment assessment and evaluation of factors influencing the outcome.

OUR STUDY

This was a mixed methods study, due to the paucity of local studies on DDT. There was a vital need to establish the prevalence of DDT in the environment of the selected communities. This Environmental exposure assessment was undertaken prior to the determination of the possible effects this could have on the infant neurodevelopmental processes. The methods and results of the initial survey have been published elsewhere [34]. The second phase was a study looking at neurodevelopmental aspects, as well as collecting of primary data to gather other supplementary information on socio-economic, residential and environmental factors that might contribute to the neurodevelopment of the infant.

The study was conducted in the Chawama and Mongu areas of Zambia, a peri-urban area in Lusaka and a mixed urban and rural area, respectively. Chawama was randomly chosen from among four other peri-urban areas, including George, Kanyama, and Garden compounds of Lusaka. Among the selection criteria considered were that they are typical townships with a high population density and a long history of IRS application and high malaria burden, and are accessible logistically.

The study could not have a non-exposed control group, since DDT may be present in the study areas due to historical exposure and its ubiquitous presence in the environment. Consequently, it is not possible to have zero exposure, as background levels may already exist in the environment and everyone's body, even without direct exposure through IRS application. In this context, Mongu was chosen as the reference area, as there had not been any recent exposure to DDT there through IRS.

The mother and child pairs were recruited from families attending antenatal clinics in the selected areas by health personnel who were incorporated into the study team. The inclusion criteria were as follows: Gave consent to participate in the study, 18 years of age and generally healthy. The only exclusion criterion was that the infant should have been a singleton birth.

The Ages and Stages Questionnaire (ASQ), which is used extensively to assess the development of children, was used for the Neurodevelopmental Assessment. Typically, this is a parent-completed, child monitoring system screening tool that uses parent/outsider observation to assess child development and behavior. Age specific questionnaires from 2-43 months are available for the assessment. Questions are written in very simple English, so that most people can complete the tool independently. The test has been validated to measure each of the five developmental domains, namely Communication, Fine Motor, Gross Motor, Problem-Solving, and Personal Social behavior of children, from one to 60 months of age. The questionnaire contains six questions in each of the five domains. Answers of "yes," "sometimes" or "not yet" are given 10, 5 and 0 marks respectively. A cut of value has been set for each domain at each age stage at 2 SD below the mean, using reference norms derived from a sample of US children. The ASQ has been validated for use in Zambia as well [35]. Clearly indicated thresholds have been set for children "below," "in need of attention" and "above" the cut off value for each domain. The test is given on an individual basis and takes about 15-20 minutes to complete.

For our study, an interview format was used, as most mothers could not read the language in the ASQ very well and, in some cases, both interpretation and translation were required. A practicing child psychologist was incorporated into the study for this assessment. The psychologist was blinded to the possible exposure status of the children to avoid bias. She presented a series of test materials to the child and observed the child's responses and behaviors while doing the scoring [36].

Information on the medical, socio-cultural and environmental factors that could modify or confound the possible neurodevelopmental effect on the children was gathered by use of an interviewer administered questionnaire. Other covariates measured for the mothers were: medical history, concomitant medicines, smoking status, level of education, employment status and level of income. For the children, a physical examination and where possible, hearing and visual screening was done given that these could affect the neurodevelopmental assessment scores.

We analyzed the data using STATA version 13. Assessment of normality for continuous variables was done using histograms. We considered the median and interquartile ranges and numbers of participants, frequencies and percentages for continuous and categorical variables, respectively. Both parametric and non-parametric analyses were employed in the study. We used the Wilcoxon Rank Sum test to explore the differences between variables of the two areas. For investigations of associations, the Chi-square test or Fishers exact test were used between categorical variables such as gender, presence of medical problems and behavior concerns. Owing to the non-normal distribution of our dataset, Spearman's Rho Correlation was used to evaluate associations between continuous variables, including all the neurodevelopment domains and maternal characteristics. Generalized linear models were used to generate a final model that would best explain the associations. We reported significant associations at 0.05 level of significance and their corresponding 95% confidence intervals.

Ethical approval was granted by the University of Zambia Biomedical Research Ethics Committee under IRB No. 0000131. Further, parents were approached in their homes by the health personnel, and the study explained to them in their local language. A copy of the Study Information Sheet was left at the home for further reference. Thereafter, if they were willing to participate in the study, they signed the IRB approved consent prior to the assessments being done. A nominal transport refund was paid to the parents to cover their cost of travel and a protein milk drink was given to the children if they had been waiting for more than an hour.

OUR FINDINGS

Out of a final sample of 104 children, the median age was 17.92 months with the youngest being two months and the oldest 42 months. The age was significantly different between sites, with Mongu having a higher median age of 21 months ($p = 0.00$). The children were evenly distributed by sex, with each area having 50% of each sex represented. More than 45% of the children were born first in their families and only 3% were born last.

Socioeconomic Status

The mothers in the study were found to have a median age of 24 [16, 53] with the Mongu mothers being slightly older, but not significantly so; 53% were married, 40% single and the rest either widowed or divorced. When it came to role in the family, more than a third of the mothers were bread winners, with 49% in informal income generating activities and 35% with some kind of family support. Only a small fraction of the women was in formal employment. It is noteworthy that there was a significant difference (<0.01) between the two areas, with more women from Mongu being bread winners and engaged in informal employment. More than half of the mother population had secondary education, and 35% had primary education, with less than 1% having no education. None of the mothers studied had any tertiary education. Table 1 summarizes the results obtained for the mothers of Chawama and Mongu.

Residential Characteristics

Almost 85% of the families lived in low cost housing, with 60% reporting that their walls were un-plastered. The difference between the areas was significant, with Mongu recording more houses with un-plastered walls. More than 67% of the mothers had lived in the area for more than four years prior to the study being undertaken. More than half of the women confirmed having used chemicals in their homes, most for pest control activities. There was a significant difference ($p = <0.01$) between the areas, with Chawama reporting a higher rate of using chemicals. This application of chemicals is in addition to the spraying conducted by the Ministry of Health annually for malaria control, of which 63% of the women affirmed having their houses sprayed in the previous ten years. The respondents in Mongu reported having a higher incidence of side effects ($p = < 0.01$), despite reporting a higher compliance rate to environmental safeguards given by the MoH prior to conducting spraying.

Table 1. Socio-demographic characteristics of mothers in Chawama and Mongu

Variable	Chawama n = 47	Mongu n = 36	Combined n = 83	p value*
Maternal age (Yrs) (Median and IQR)	24 (19-46)	25 (16-53)	25 (16-53)	0.63

20-30\$	12	21	33	
30- 50\$	5	5	10	
50\$	9	5	14	
	21	5	26	

* Wilcoxon Rank Sum test was used in all data analysis in this table.

With regards to access to drinking water, 74% of the mothers stated that they had a water source within the proximity of their homes. About 41% of the respondents affirmed the presence of a variety of vegetables (26%) and tubers, such as cassava and sweet potatoes (11%), with the rest being maize, as growing within the vicinity of their houses. Only 23% of the mothers reported the presence of any livestock around the houses, most of which were chickens and pigs.

Maternal Characteristics

Almost all (99%) of the mothers had had access to antenatal care at the health facility during their pregnancies. However, close to half of the mothers (39%) confirmed having suffered from some type of complication during pregnancy, which ranged from malaria, high blood pressure, and taking some kind of medication during the pregnancy, ranging from anti-malarial drugs, antibiotics, nutritional supplements, and anti-retroviral drugs.

None of the mothers reported smoking during the pregnancy, although 11% acknowledged consuming alcohol during the pregnancy. There were 23% of homes where another member of the family smoked, thereby potentially exposing the unborn baby to passive cigarette smoke.

Infant Neurodevelopmental Scores

The children's neurodevelopment scores were categorized into the 18 age groups provided in the ASQ. While 22% of the scores were above the cut off points for those specific ages, more than 50% of the children's scores lay in the gray area which stipulates that the children required further assessment and attention. The last 22% were the children below the cut off scores for those age groups. At six months of age, median scores for fine motor and personal social were below the cutoff points as were those for gross motor at 22 months. The children from Chawama were found to score higher in all the neurodevelopmental domains compared to those of Mongu. These differences are statistically significant for all domains except for fine motor domain. Table 2 provides the summary scores and Figures 2 and 3 show medians and IQR for each age group.

Table 2. Neurodevelopment assessment scores for selected children in Chawama and Mongu: Scores are summarized across ages

ND Scores*/**	Chawama	Mongu	Combined	p value***
Communication	55 (5, 50)	45 (10, 60)	50 (5, 60)	<0.01
Gross Motor	55(0,60)	45 (10, 60)	52.5 (5,60)	<0.01
Fine Motor	50 (0,60)	45 (10, 60)	45 (0,60)	0.09
Problem Solving	50 (0, 60)	35 (0, 60)	40 (0, 60)	<0.01
Personal Social	50 (0, 60)	40 (5, 60)	45 (0,60)	< 0.01

* A cut of value set for each domain at 2 SD below the mean, using reference norms from a sample of US children. The scores are given to a maximum of 60.

**Scores are reported as medians and IQRs.

***Wilcoxon Rank Sum test.

Usage of Chemicals

Multiple weak non-statistically significant negative correlations were found between use of chemicals and all domains of neurodevelopment. Upon stratifying by sex, the results showed more negative associations with males in all domains with personal social being significant ($\rho = -0.34$, $p = 0.02$). After categorizing the neurodevelopment scores by age, at

27 months, use of chemicals was significantly negatively correlated with all domains; these were significant for communication and personal social ($\rho = -0.85$, $p = 0.03$ and $\rho = -0.84$, $p = 0.03$) respectively. When categorized according to the area, the children from Chawama had more negative associations in all domains when compared to those of Mongu, who only showed weaker negative correlations in gross motor and personal social behavior.

Figure 2. Children’s neurodevelopment scores at each age group (Figure 2a) and summarized (Figure 2b).

Figure 3. Associations of maternal characteristics with child neurodevelopment scores.

Socio-Economic Status

Maternal age was negatively associated with problem solving and none of the other functions. Marital status was found to influence all domains negatively with higher scores being found among children born of married mothers. The role the mother plays in the family was found to be ($p = 0.06$) associated with problem solving skills in the children, with the higher scores found in children whose mothers were dependents. Positive associations were found between educational level of the mother and problem solving ($p = 0.07$) and personal social behavior ($p = 0.08$), with children of mothers who had secondary education scoring higher points in these domains. Source of income, level of income, and type of house did not seem to influence any of the domains significantly.

Medical Factors

No significant associations were found between complications during pregnancy and any of the neurodevelopmental domains. Mode of delivery seemed to have a weak association with personal social behavior, as could be seen with children born of vaginal delivery doing better than those born of Caesarian section. The taking of vitamin supplements and anti-malarial drugs seemed to have a positive significant influence on gross motor, fine motor and problem solving scores. None of the other medical factors had any significant influence on the children's ASQ scores in all the domains.

Housing and Environmental Factors

None of the variables showed any significant influence on the neurodevelopmental scores. However, it is worth noting that there was more chemical usage in the low cost homes with unplastered walls.

Generalized linear models showed that the strongest predictors of the children's neurodevelopment were mother's marital status, role in the family, income levels and type of house. The area of chemical application was also found to be a significant factor.

DISCUSSION

The neurodevelopmental scores for the two areas show significant differences, with the Chawama children obtaining higher scores than their Mongu counterparts. This is despite the fact that Chawama children had recent exposure to DDT and its metabolites, and the presence on previous environmental exposure assessments of much higher DDT levels in the soils and water samples from Chawama when compared to Mongu [34]. It gives credence to the arguments advanced by other scholars that SES is an important determinant of an infant's neurodevelopment. SES in addition to being a confounder may also be an effect modifier to the health effects of chemicals [37, 38].

That notwithstanding, the correlations found in this study, albeit not statistically significant, point to the plausibility of a negative association between use of chemicals and child neurodevelopment. Given a larger sample size of participants, these correlations might rise to the level of statistical significance. These seem in addition to maternal and housing factors to be influenced area and age differences. This trend has been observed in previous studies which show significant negative associations between DDT/DDE levels in biological matrices and infant neurodevelopmental outcomes. A few of these have adjusted for socio-economic factors, such as maternal age and IQ. However, all these studies were carried out in the Western world where Socioeconomic Status are vastly different from those found in Zambia, a typical developing country. Our study has also revealed that, despite being better off socio-economically, compared to the Western world, the children in Chawama had lower minimum scores in almost all the domains.

The Mongu mothers from our study, were mostly single mothers who were also the bread winners of their families and subsequently engaged in informal income generating activities. This might explain the negative significant association found with the problem solving and personal social functions of their children. Black et al. [39] in discussing their 2000 study conducted on 87 children and toddlers from low income families, state, "Children who are raised in poverty may be particularly vulnerable if their caregivers are unable to provide the enriching environment that toddlers need to develop the language and problem-solving skills that emerge in the second year of life" [39]. The other reason put forward is that children growing up in resource-constrained settings are usually left in the care of older siblings or domestic helpers. These caregivers may not have the requisite characteristics or time to provide enough stimulation to the child and engage them in activities that will offer them opportunities for learning and refining of problem solving and personal social skills. [39].

Koutra et al. [1] show that, in a Greek cohort of 605 mother and child pairs, maternal characteristics played a big role in infant neurodevelopment. Using the Bayley Scales of Infant Development (BSID), they found that higher maternal education level is positively correlated with almost all the neurodevelopmental domains assessed. In contrast to our study, they found that a mother's employment status seemed to also have a positive effect on the children's performance. This finding is explained in part by Van Heerden et al. [35], who postulate that children raised by stay-at-home mothers spend a lot of time with their mothers, and this close proximity helps the babies feel secure. This, according to them, may be responsible for the early advances seen in most domains by the children from Chawama, whose mothers were mostly dependents.

The cultural and social differences between Chawama and Mongu may also partially explain the results that were obtained. The ASQ questionnaire is in English, and therefore requires translation in the local language. Chawama mothers being in the capital city, Lusaka, could understand some English and most of them spoke the language familiar to the child psychologist. In contrast, the Mongu mothers did not speak much English and the local language was not very familiar to the administrator; thus, a member of staff at the health center was co-opted to translate the questions. In addition, some of the test items such as the "piggy bank" and games like "peekaboo" are not widely used in rural Zambia. This could have also hindered the understanding of the children, thereby lowering their overall performance. Some of the test items, particularly as they relate to color identification, ordering building blocks, and others, could have also been unfamiliar to the children, thereby affecting their performance in the problem solving domain [35].

Other potential effect modifiers including childhood illnesses, nutrition and HIV status were not measured in this study. These have been shown elsewhere to affect infant neurodevelopment.

CONCLUSION

Taken in totality, 55% of the scores of all the children are in the range that requires attention and further assessment. We believe that this demonstrates that many children of Zambia are still at risk, despite lack of evidence that recent exposure to DDT is significantly influencing their developmental growth.

There is an urgent need to take a wider view in solving the malaria problem in Zambia, starting with investments which will improve the lives of women. Improving their housing and improving their educational status would help to provide a secure and nourishing environment necessary for a child's development. Our study suggests that, as demonstrated in studies in other cultures as well, there is a much stronger influence from maternal characteristics on their children's development. Improving socio-economic factors, including better education, employment options and marital status, will afford mothers more contact time with children. The increased income could break the cycle of the disparities related to housing and environmental factors. The health risks to the mothers and children may be significantly reduced by addressing these very fundamental needs.

Chapter 262

RACIAL DISPARITIES IN ACCESS TO MUNICIPAL WATER SUPPLIES IN THE AMERICAN SOUTH

Frank Stillo, MSPH and Jacqueline MacDonald Gibson*, PhD

Gillings School of Global Public Health, Department of Environmental
Science and Engineering, The University of North Carolina at Chapel Hill,
Chapel Hill, North Carolina, USA

ABSTRACT

More than five decades after the Civil Rights Act, systematic exclusion of African-American neighborhoods on the fringes of cities and towns from municipal services, including water service, continues. Throughout the American South, many such neighborhoods still rely on unregulated private wells for their drinking water despite their close proximity to municipal water lines. Little is known about water quality, including lead contamination, in these communities. In this chapter kitchen tap water samples were collected and tested for lead in 29 households recruited from peri-urban African-American communities in Wake County, North Carolina, relying on private wells. The Integrated Exposure Uptake Biokinetic (IEUBK) Model for Lead in Children was used to estimate blood lead levels in children resulting from lead in water. Results: In eight (28%) of the 29 households, tap water lead exceeded the 15-ppb health-based action level in at least one of two samples. In seven homes, the average lead in two samples exceeded 15 ppb. The IEUBK model predicts that in 3 (10%) of the households, water lead could elevate children's blood lead above the current 5 µg/dL reference level. Discussion: The lead prevalence in households in this study was comparable to that in the most-exposed neighborhoods of Flint, Michigan, during the recent lead-in-water crisis. These results indicate the need for interventions to decrease lead exposure in peri-urban African American communities excluded from nearby municipal water service.

INTRODUCTION

Several studies in the last 30 years have documented the systematic exclusion of African-American neighborhoods on the fringes of cities and towns from access to municipal services, including water and sewer service, trash collection, paved roads, and police and fire protection [1–6]. Demographer Charles Aiken termed this exclusionary zoning practice “municipal underbounding” [1]. Aiken and others have documented instances in which cities and towns gerrymandered their boundaries to leave out African-American neighborhoods, even when those neighborhoods were fully enclosed by town boundaries [1–3, 5–8]. Because they lack access to municipal water and sewer service, underbounded neighborhoods rely on private wells for their potable water and on septic systems for their sewage disposal—even though their neighborhoods may be encircled by water and sewer pipes. Unlike in adjacent neighborhoods included within municipal boundaries, each underbounded household must operate and maintain its own private well and septic system, without financial or technical assistance.

Figure 1. Cycle of environmental and health disparities experienced by communities that remain excluded from municipal services on the basis of race. Educating the communities and public health officials on well water quality and subsequent health effects can help to break this cycle of disparity.

Little is known about drinking water quality in underbounded neighborhoods, in part due to lack of private well monitoring [9]. To our knowledge, only three previous research studies have tested water quality in such neighborhoods [4, 10, 11]. The most recent study (by our team) tested 57 wells in underbounded communities in Wake County, NC, for microbial contaminants; we found contaminants in tap water in 37 (65%) of the households [10]. A 2011 study of an underbounded community in Alamance County, NC, found that 6 (13%) of private well samples tested positive for both fecal coliform and *E coli* bacteria. [11] A 2013 study of the underbounded Rogers-Eubanks community in Orange County, NC, tested for

microbial and selected chemical contaminants in 12 wells [12]. This study found fecal coliforms in 5 (42%) of the wells. In addition, in several wells, concentrations of selected metals exceeded federal recommended drinking water limits: five for iron and manganese and one for lead. The nearly uniformly low pH of water from these wells—11 of 12 were below the federally recommended lower limit of 6.5 pH units—suggested high potential for plumbing corrosion to serve as a continuing source of metals.

In the current study, we examine lead contamination in private wells and the contribution of water lead exposure to health in children 6-84 months old in underbounded neighborhoods of Wake County, NC, excluded from municipal water service. Recent events in Flint, MI, have renewed attention to water as a potentially important source of exposure to lead, a long-established neurotoxin even at low levels [13, 14]. On average, lead levels in African-American children are higher than in white or Hispanic children [15]. It is possible that disparities in lead exposure via drinking water could in some cases contribute to this racial disparity in children's blood lead. The aforementioned study in the Rogers-Eubanks community suggests the potential for increased lead exposure in water in underbounded communities, but apart from that study, no research on lead exposure in water in such communities has occurred. The Rogers-Eubanks study may have underestimated lead exposure risks because some samples were collected at the well head or from an outdoor spigot, rather than from an indoor tap, and in all cases the water was run for three minutes prior to sample collection. Flushing of samples and collection from the wellhead rather than the household tap can mask the presence of lead and other metals introduced through corrosion of household plumbing [16]. In this study, we evaluate the concentration of lead in unflushed, indoor tap water samples in 29 underbounded households. We then estimate how lead exposure via drinking water in these households could affect blood lead levels and IQ in children aged 6-84 months.

CYCLE OF CHILD ENVIRONMENTAL HEALTH DISPARITIES

Currently, residents in racially underbounded communities face a cycle of environmental disparities, in comparison to neighboring communities that are included within municipal boundaries. One disparity (shown in Figure 1) with potentially important impacts on children's health is the lack of protections afforded to municipal water system customers under the EPA Lead and Copper Rule [17], established in 1991 to prevent lead exposure in drinking water. Under the Lead and Copper Rule, all large community water systems (those serving more than 50,000 people) must treat their water with corrosion inhibitors to prevent lead release from water distribution pipes and household plumbing. In addition, all community systems, regardless of size, must monitor tap water for lead every six months in multiple households throughout their distribution networks, focusing on houses that, due to their age, are most likely to have leaded plumbing or solder. If lead concentrations exceed 15 ppb (the EPA action level) in 10% or more of the samples, then the water utility must implement corrosion control (if it has not done so already), optimize its existing corrosion control, and/or replace lead service lines.

Data from selected municipal water utilities suggest that the preventive measures established under the Lead and Copper Rule have substantially decreased lead exposure in

drinking water in households with access to municipal water infrastructure. For example, in New York City, average tap water lead concentrations decreased by 62% (from 4.0 to 1.5 ppb) between 1992 and 2003 due to the addition of orthophosphate corrosion inhibitors to the treated drinking water [18]. The recent lead-in-water crisis in Flint illustrates that lead exposure concerns may remain in some municipal water systems. Nonetheless, the Flint crisis represented an extraordinary occurrence, in which the city failed to implement adequate corrosion control as part of a cost-saving measure initiated by financial managers who took over the city during bankruptcy and in which subsequent data that would have alerted officials to the lead problem were concealed [19, 20]. In general, compared to households relying on private wells, those with municipal water service have the benefit of regular water quality monitoring and centrally managed corrosion control to prevent lead exposure in drinking water.

As shown in Figure 1, lack of municipal water system access could lead to an increased risk of exposure to lead in drinking water, due to the leaching of lead from well components or household plumbing in the absence of adequate corrosion control. Private well households typically lack the knowledge and/or the means to adequately monitor their water quality and to install and maintain appropriate treatment when water quality problems are discovered [21–23]. Many private wells deliver water with low pH, increasing the risk of lead corrosion, compared to higher pH waters or waters to which corrosion inhibitors have been added [24]. In turn, an increased risk of exposure to lead—even at low levels—increases the risk of permanent loss of intellectual function and behavioral disturbances among children [14, 25, 26]. The identification of lead exposure in drinking water has already helped other communities, like Flint, appreciate and begin to act in an attempt to provide safe drinking water to the community. Educating private well owners and public health officials of lead exposure risks and health effects in underbounded communities can help break the cycle of children’s environmental health disparities in these marginalized communities.

OUR STUDY

To characterize lead exposure risks in drinking water in underbounded African-American communities, we conducted a pilot study involving 29 households recruited from majority African-American census blocks within the municipal extraterritorial jurisdictions of Wake County. In North Carolina, municipalities can control zoning and land use decisions in extraterritorial jurisdictions at a distance of up to 3 miles from city boundaries, depending on population size, without providing municipal services (including public water supply) or voting rights in municipal elections [27]. The 57 participants from our previous study of microbiological water quality in underbounded communities [10] were each contacted by telephone to inquire about their interest in the present study. The first 29 to respond and agree to participate were enrolled (available resources could support sampling only in 29 households). Participants received a \$25 gift card as compensation after completing a survey following water sample collection. This study was approved by the University of North Carolina, Chapel Hill, Institutional Review Board.

Water Sample Collection

All household water samples were collected during August 2016. One day before sample collection, sample kits were delivered to each household. The kits included detailed instructions for collecting first-draw morning samples from the kitchen tap after an overnight stagnation period and two 10-mL metal-free sampling vials (VWR, Radnor, PA). Instructions for sample collection followed the Environmental Protection Agency's (EPA) Lead and Copper Rule Sample Collection Form [28], with the exception of the size of the sample collection bottles (smaller than 1 liter). Consistent with EPA-recommended procedures, instructions directed homeowners to collect samples from the kitchen tap using cold water after a minimum 6-hour stagnation period. Participants were instructed to fill both vials without flushing and to label each vial with the date and time. The filled vials were then collected by research staff on the same day. After collected vials were transported to the lab, each 10-mL vial was digested in 70% concentrated nitric acid to a 2% by volume solution for a minimum of 24 hours.

Quantification of Lead

Metals (lead along with aluminum, cadmium, copper, nickel, and zinc) were analyzed using standard methods [29] using an inductively coupled plasma mass spectrometer (Agilent Technologies 7500cx, Santa Clara, Calif.). Validity of the data was assessed through analysis of replicate samples (10.3% of total samples), quality control standards spanning concentration ranges of analytes, and blanks. Quality control standards were prepared from National Institutes of Standards and Technology traceable solutions (High Purity Standards, Charleston, SC, USA). The statistical package *R* was used to calculate summary statistics for lead and other metals.

Comparison to Lead in Municipal Water and in Wells Outside Study Communities

To compare water lead in the study communities to that in nearby homes served by the Raleigh municipal water supply, we extracted data on lead concentrations in Raleigh municipal water from the Safe Drinking Water Information System (<https://www.pwss.enr.state.nc.us/NCDWW2/>). We obtained all lead measurements collected during 2016 in single-family households throughout the Raleigh water distribution system (65 samples in total). All sampling locations were labelled as Tier 1, meaning the Raleigh Public Utilities Department has identified them as at highest potential risk of lead exposure in water due to the age and type of the household plumbing and/or service lines delivering water to the homes. All reported samples were first-flush samples collected from the kitchen tap.

We obtained summary statistics on lead concentrations in private wells throughout Wake County from the NC Division of Public Health (NCDPH). The NCDPH maintains a web site (http://epi.publichealth.nc.gov/oe/wellwater/by_county.html) with summary statistics for private well water samples tested by the State Laboratory for Public Health during 1998-2010. In total, the state lab tested 3,188 well water samples for lead during this time period.

Health Impact Assessment

To estimate potential impacts of lead in drinking water on children's blood lead levels, measured water lead concentrations for each household were input into the Integrated Exposure Uptake Biokinetic Model for Lead in Children (IEUBK; U.S. EPA 2010, *IEUBKwin32* Lead Model Version 1.1 Build 11) [30]. This physiologically based pharmacokinetic model compartmentalizes the human body and predicts the absorption, distribution, metabolism and excretion of lead. The IEUBK model estimates the predicted geometric mean blood lead level for children aged 6-84 mo., in one-month age groups, for a given level of exposure to lead from drinking water and other sources (soil, dust, and air) that the user can specify. The model also estimates the probability of a child in each one-month age group having a blood lead level greater than 5 µg/dL, the current reference level recommended by the Centers for Disease Control and Prevention (CDC) for identifying elevated lead exposure risks. For each household, we ran the IEUBK model twice for each of the two water samples: once using the average water lead level measured in the two samples while assuming no lead exposure from other sources and a second time including the model's default assumptions for lead exposure from soil, dust, and air (200 µg/g, 150 µg/g and 0.1 µg/m³, respectively). These results were used to estimate the expected excess blood lead attributable to water alone and the chance that water lead exposure could cause a child's blood lead to exceed 5 µg/dL, when considering water exposure and exposure from other sources.

To estimate the potential effects of the estimated blood lead levels on children's IQ, we used the multiple regression model from Lanphear et al. [25]. The model was run for each household and each one-month age group. The model form is:

$$\text{IQ Loss} = \beta * \text{Ln}(BLL_{ij}) \quad (\text{Equation 1})$$

where $\beta = -2.70$ (95% CI = -3.74 to -1.66) is the coefficient from Lanphear et al. for mean adjusted changes in full-scale IQ score associated with an increase in blood lead concentration [25] and BLL_{ij} is the blood lead concentration estimated by the IEUBK model at household i for age j (in months). Uncertainty in the estimated IQ loss was estimated via Monte Carlo simulation using *Analytica* (Lumina Decision Systems, Los Gatos, CA) (10,000 iterations per household). In the Monte Carlo simulation, β was represented as normally distributed (mean = -2.70, standard deviation = 0.531). Blood lead levels were estimated as lognormally distributed using the geometric mean estimates from the IEUBK model output and a geometric standard deviation of 1.6 µg/dL (as specified in the IEUBK model user manual) [30].

OUR FINDINGS

Enrolled participants were located throughout underserved areas of Wake County. As Figure 2 illustrates, participating households were in neighborhoods that are surrounded by areas with community water supplies, as indicated with blue shading. However, these households lack access to the nearby community water supplies.

Figure 2. Locations of the 29 households participating in this study. Dark blue shading indicates areas that are within municipal boundaries. Participating households were not located within municipal boundaries, even if very close to those boundaries, as shown in the insets. Light blue shading indicates areas that are within extraterritorial jurisdictions of municipalities (meaning the municipalities control land use decisions in those areas) but have community water service, even though they are outside of town boundaries. Yellow areas and all participating households are in extraterritorial jurisdictions but lack community water service.

Table 1. Characteristics of study participants and their wells

	Study Participants	Wake County	<i>p</i> Value for Difference
Race (n = 21)			
Black/African-American	62%	21%	<0.001
White	33%	69%	<0.01
Asian/Asian American	5%	7%	NS
Other	0%	3%	NS
Education (n = 20)			
High school or higher	95%	92%	NS
Bachelor's degree or higher	60%	49%	NS
Home ownership (n = 20)	100%	64%	<0.01
Median household income (n = 20)	\$62,500	\$67,309	NS
Median age of well (n = 19)	30 years	NA	NA

Note: Some participants did not respond to the demographic questions on our survey. Numbers responding to each question are indicated in parentheses. NS = not significant; NA = information not available.

Among participating households, a significantly ($p < 0.001$) higher percentage (62%) identified as African American than in Wake County (21%) (see Table 1). The median household income among participants (\$62,500) was slightly lower than that in Wake County (\$67,309), although this difference was not statistically significant. The study population had a larger proportion with bachelor's degrees or higher (60%) than Wake County as a whole (49%), but this difference was not statistically significant. The study population had a much

higher rate of home ownership than Wake County (100% as compared to 64%, $p < 0.01$). This latter finding is consistent with previous studies of racially underbounded communities in North Carolina [3, 31], which have documented generations of land ownership within the same family, in some cases dating back to land granted to freed slaves after the Civil War. Current patterns of racial underbouding thus have longstanding historical roots.

Lead Prevalence

To evaluate exposure to lead in drinking water in the participating households, two first-flush water samples were collected from the kitchen faucet and analyzed for lead. In eight (28%) of the households, the tap water lead concentration exceeded the 15-ppb health-based action level in at least one of the two samples. In seven (24%) of the homes, the average of the two samples exceeded 15 ppb (see Figure 3). Across all 58 samples, the average concentration was 8.19 ppb, and the maximum was 79.4 ppb (see Table 2).

Figure 3. Average concentration of lead in tap water from 29 households, each sampled twice, in African American peri-urban communities excluded from the public drinking water system in Wake County, NC, USA. U.S. Environmental Protection Agency (EPA) action level is health based standard for drinking water.

Table 2. Metals (µg/L) in drinking water in private wells in peri-urban areas of Wake County, NC (n = 29)

Constituent	Mean	Median	Max	Standard ^a	Samples Exceeding Standard
Aluminum	36.3	6.50	436	50-200 (NSDWR)	3.45%
Cadmium	0.591	0.0355	19.7	5 (MCL)	1.72%
Nickel	8.57	1.17	129.1	NA	NA
Zinc	1,562	388	9,346	5,000 (NSDWR)	12.1%
Copper	629.5	135.4	5,645	1,300 (action level)	10.3%
Lead	8.19	3.00	79.4	15 (action level)	15.5%

^a MCL: Maximum Contaminant Level, established for contaminants associated with risk to human health. National SMCL: Secondary Drinking Water Standard, established for contaminants that may cause aesthetic problems. Action level, established for contaminants regulated on the basis of treatment technologies; if exceeded in more than 10% of homes, the system must undertake additional action to control corrosion and inform the public.

Lead Sources

To evaluate potential lead sources, we also tested concentrations of other metals known to be associated with plumbing corrosion (see Table 2). We found strong and statistically

significant ($p < 0.01$) correlations between lead and zinc ($\rho = 0.51$), nickel ($\rho = 0.49$), and aluminum ($\rho = 0.34$) (see Figure 4).

The high correlation with zinc suggests that corrosion of galvanized pipes may be a lead source. Galvanized pipes are lined with a zinc coating also containing up to about 2% lead. Recent research has concluded that these pipes can be a major source of lead in drinking water [32].

To further explore the hypothesis that galvanized steel is a lead source, we compared the lead concentrations in samples without and with detectable cadmium, which can serve as another marker of galvanized steel corrosion [32]. The mean lead concentration in the 11 samples without detectable cadmium was 0.607 ppb. By comparison the mean lead concentration in the 47 water samples also containing cadmium was 9.96 ppb—16 times higher than in the samples without cadmium. This difference was highly statistically significant (one-tailed t -test $p < 0.0001$), even though the concentrations of lead and cadmium were not significantly correlated ($\rho = 0.075$, $p = 0.57$). The finding of much higher lead concentrations in samples with cadmium than in those without supports the hypothesis that galvanized steel corrosion may be introducing lead into the water.

Corrosion of brass fittings, which contain 60-80% copper along with zinc (4-32%) and lead (2-8%), could be another lead source [24]. The presence of high copper concentrations in some of the samples (with 10% exceeding the federally recommended action level of 1300 μL , as shown in Table 2) indicates potential brass corrosion. However, the correlation between lead and copper ($\rho = 0.21$) did not reach statistical significance.

Other potential sources include lead solder and nickel-plated brass, the latter suggested by the significant correlation ($\rho = 0.49$) between lead and nickel.

Comparison to Lead in Municipal Water and in Other Wake County Private Wells

To compare lead concentrations in the study households to concentrations in households served by municipal water supplies and in other Wake County households with private wells, we extracted water sample test results from relevant NC databases. The average lead concentrations in the study households is nearly three times as high as in households served by the City of Raleigh municipal water supply (8.19 vs. 2.83 ppb, $t = 2.38$, $df = 46$, $p = 0.01$). In addition, the proportion of households testing above the 15-ppb action level is significantly higher in the study sample than in community samples (24% versus 1.5%, chi-square = 13.2, $df = 1$, $p = 0.00014$). The average concentration in the study households is greater than that in the 3,188 Wake County wells tested between 1998 and 2010 (8.19 vs. 7.8 ppb), but this difference is not significantly different. However, the proportion of wells exceeding 15-ppb in the study samples is nearly five times higher than in the other Wake County wells (24% versus 5.4%, chi-square = 19.2, $df = 1$, $p = 5.8 \times 10^{-6}$). These results indicate that lead exposure risks in drinking water are higher in the underbounded neighborhoods of this study than in neighborhoods served by the Raleigh municipal water supply and also are higher than in other areas of Wake County served by private wells (for example, rural areas outside of municipal extraterritorial jurisdictions).

Figure 4. Bivariate correlation plots of metals in tap water from 29 households, each sampled twice, in African American peri-urban communities in Wake County, NC, relying on private wells. Ellipses show 95% confidence regions; red dots are confidence region centroids.

Health Impacts of Lead Contamination

To estimate the potential impact of lead contamination on children's health in the participating households, we applied the IEUBK model to predict the how the observed water lead levels could affect the concentration of lead in children's blood. Among the 29 households, considering children aged 6 months to 7 years, the average predicted blood lead level arising from water lead alone was 1.06 $\mu\text{g}/\text{dL}$, and the maximum was 4.55 $\mu\text{g}/\text{dL}$.

Figure 5. Predicted blood lead levels in children consuming water with lead levels as measured in the study households.

Because exposure to lead in water must be considered in the context of other lead sources, we also evaluated whether exposure to lead in water could elevate a child's blood lead above the CDC high-blood-lead threshold of 5 $\mu\text{g}/\text{dL}$, when added to lead exposure from other sources. On average across households and ages, the IEUBK model predicted that blood lead levels would be 3.03 $\mu\text{g}/\text{dL}$, when considering combined lead exposure from water, soil, dust, and air, with a maximum of 6.88 $\mu\text{g}/\text{dL}$. Figure 5 shows that predicted blood-lead levels are highest for children aged 18 months. For this age group, the contribution of lead from water results in a total blood lead level of greater than 5 $\mu\text{g}/\text{dL}$ in three households (see Figure 6). In another five houses, water lead in combination with lead from other sources results in a predicted blood lead level within 1 $\mu\text{g}/\text{dL}$ of the 5 $\mu\text{g}/\text{dL}$ threshold among 18-month-old children.

For each household, we also used the uncertainty features in the IEUBK model to estimate the probability that the child's blood lead level could exceed 5 $\mu\text{g}/\text{dL}$. On average across all households and age groups, the risk that water lead alone will result in a blood lead levels above 5 $\mu\text{g}/\text{dL}$ is 1.9%. Across households and among 18-month-old children, the IEUBK model predicts a 3.1% risk of having an elevated blood lead level from water lead alone, on average, and a 42% risk of exceeding this threshold in the highest-risk household

(see Figure 7). When considering water in addition to other lead sources among 18-month-olds, the average probability that blood lead levels will exceed 5 $\mu\text{g}/\text{DL}$ is 30% across the 29 houses, with a probability greater than 50% in three homes and a maximum of 75%.

Figure 6. Predicted median blood lead levels in 18-month-old children consuming water with lead levels as measured in the study households.

Figure 7. Predicted probability that blood lead in an 18-month-old child in the stuy households will exceed the 5 $\mu\text{g}/\text{dL}$ reference level established by the Centers for Disease Control and Prevention.

Figure 8. Predicted median IQ loss associated with exposure of an 18-month-old child to environmental lead in the study households. NOTE: Error bars represent 95% confidence intervals on total IQ loss.

To estimate the potential effects of lead on childhood IQ, we combined the IEUBK model output with statistical estimates of the relationship between blood lead and IQ developed by Lanphear et al. [25] Across households and among 18-month-olds, the mean predicted IQ loss attributable to water alone was estimated to be -0.86 IQ points (median = -0.24), with the highest household exposures resulting in an estimated mean -4.1 IQ points (median = -4.0) lost attributable to water alone (Figure 8). When considering total exposure to lead (water in addition to the default assumed background exposure from other sources), the mean IQ loss across all 29 households was -3.6 points (median = -3.4). The mean value in the highest-risk household was -5.2 points (median = -5.1) (see Figure 8). Previous studies have indicated a decrease of about 2% in lifetime earnings with each one-point decrease in IQ. [33] As a result, a child relying on water from this highest-risk household could experience a decrease of more than 10% in lifetime earnings.

DISCUSSION

Our results suggest that lead contamination is prevalent at concentrations that exceed the EPA 15-ppb action level in racially underbounded Wake County, NC, neighborhoods excluded from municipal water service. Lead exposure in these communities may increase the risk of elevated blood lead levels in young children, potentially causing permanent neurological damage. Exposure to lead in water is just one of the environmental disparities these communities may face. Our previous research, for example, documents a much higher risk of exposure to bacterial contaminants in drinking water in underbounded communities of Wake County than in areas served by municipal water supplies [10]. It is possible that

exposures to other drinking water contaminants may be higher, as well, but these exposures have yet to be assessed. The potential for synergistic effects resulting from these exposures is unknown.

Notably, the prevalence of elevated waterborne lead in the samples we collected is similar to that observed in Flint during the recent water crisis. At least one of the two samples we collected exceeded the 15-ppb action level in 8 (28%) of the 29 houses we sampled. By comparison, Hanna-Attisha et al. [34] reported that during the Flint water crisis, the percentage of samples with lead above 15 ppb ranged from 10–32% across Flint's nine wards; they defined wards with more than 25% of samples having elevated lead as “high water lead-level (WLL)” areas. By this definition, the underbounded communities we sampled would qualify as having high WLL.

Our water quality results show a somewhat higher lead prevalence than observed in previous studies of rural private wells. A study of private water systems (private wells, springs, and cisterns) in the rural Blue Ridge-Piedmont region of Virginia found that 19% of 2,144 households tested had lead levels above 15 ppb [24]. A study of 251 Pennsylvania private wells reported 12% of households had elevated water lead levels [35]. Variation in lead prevalence, as suggested in both studies, could be the result of private water system characteristics (e.g., well type, plumbing components, use of household filters) [24, 35] and geologic characteristics (e.g., pH, alkalinity) of the aquifer from which the wells draw their water [36]. Both studies found that household age was highly correlated with lead concentration: the Virginia study found that lead concentrations were significantly higher in homes built before 1988 than in those constructed after 1988, and the Pennsylvania study reached a similar conclusion for houses constructed before 1991 as compared to after 1991. The authors of the Virginia study suggested that these differences could “reflect the 1986 Lead Ban, which required the use of ‘lead-free’ plumbing components in the installation or repair of any . . . residential building . . . connected to a municipal system after June 1988.” The authors suggest that although the lead ban did not apply to private wells, the increased demand for lead-free components could have influenced the availability of such components for newer private well households. Half of the wells included in our study were constructed before the lead ban.

Like the Virginia study, our results also suggest corrosion of plumbing components as a likely lead source. The Virginia study found strong ($\rho > 0.50$) and statistically significant correlations between lead and zinc, copper, and nickel (in order of decreasing correlation) and a weak but significant correlation between lead and aluminum ($\rho = 0.27$). Similarly, our study found a strong ($\rho = 0.51$) correlation between lead and zinc and significant but weaker correlations between lead and aluminum and nickel. The Virginia study authors noted that brass is composed largely (60–80%) of copper and also includes a large proportion of zinc (4–32%), along with lead (2–8%); on this basis, they hypothesized that brass plumbing is a major lead source. The relatively low and statistically insignificant correlation between lead and copper in our study ($\rho = 0.21$) could suggest that components other than brass are a more important source of lead in these households, compared to in the Virginia households.

To our knowledge, only one previous study has analyzed water samples for lead in underbounded African-American neighborhoods excluded from community water service [4]. The previous study found that 1 of 12 private wells in the Rogers–Eubanks community in Orange County, NC, exceeded the 15 ppb action level [4]. However, some of the samples

were collected from the wellhead or outdoor spigot, rather from an indoor tap, therefore overlooking household plumbing as a lead source. In addition, water taps were flushed for three minutes prior to sample collection, also potentially masking key lead sources and underestimating the prevalence of lead [37].

The IEUBK model prediction that water lead in the underbounded households in this study would increase the risk of elevated BLL by 1.9%, on average, in children ages 6-84 is similar to the 2.5% observed increase in the prevalence of elevated blood lead levels in Flint during the water crisis [34]. The model prediction that children in this community would, on average, have blood lead levels of 3.03 $\mu\text{g}/\text{dL}$ is similar to the concentration of 2.4-3.4 $\mu\text{g}/\text{dL}$ predicted by the IEUBK model for a sample of children in Montreal households, the majority of which had lead service lines [38].

Limitations

There are a number of limitations of our study. The samples were collected in August, when temperatures in NC peak and lead releases are expected to be highest. As a result, exposures during other months could be lower. On the other hand, samples were collected at low flow rates due to the small mouths of the sample collection bottles, which could have underestimated exposures due to lower release of lead particles than occurs under standard water flow rates. Similarly, the sample collection bottles we used were smaller than the 1L wide-mouth containers the EPA recommends (although there are no standardized sampling protocols for private wells). Lack of temporal sampling may have resulted in an underestimate of particulate lead due to the failure to capture episodic releases of lead particles.

Our estimates of blood lead levels and associated IQ impacts are based on models rather than measurements. The background exposure to soil and dust lead assumed in the IEUBK model, and used in our analysis, could be too low, especially given the older age of some of the households in our study. For example, Lanphear et al. [26] reported that measured soil lead concentrations were more than 12 times as high as default assumptions in the IEUBK model. In addition, a previous systematic review of racial and ethnic differences in childhood blood lead levels found that African-American children have the highest mean blood lead levels [39], but the IEUBK model does not account for the effects of race. At the same time, the IEUBK estimates of the probability of having lead above the CDC reference level (5 $\mu\text{g}/\text{dL}$) do not agree with observed data from blood lead monitoring in Wake County. From 2011-2015, 96 out of 10,294 children (0.933%) tested in Wake County had blood lead levels above 5 $\mu\text{g}/\text{dL}$ [40]. On the other hand, this sample of children may not be representative of the underserved communities in this research.

CONCLUSION

Our results suggest that many homeowners in underbounded communities of Wake County, NC, are not adequately managing lead corrosion within their private well water system. Children in these communities potentially face increased risk of exposure to lead

compared to neighboring children consuming municipal water, with 24% of the study households exceeding the 15-ppb action level for lead in water, in comparison to 1.5% of households served by the nearby Raleigh municipal water supply. In addition, these children may be at increased risk of exposure to lead from sources other than water due to the older housing in their neighborhoods. The lead exposure risks may be a legacy of a practice of municipal underbounding, contributing to a continuing cycle of increased exposure to environmental lead. To break the cycle of increased risks in these communities, financial and technical support may be needed to enable communities to either advocate for connections to the municipal water supply or to follow recommended well water testing, treatment, and maintenance procedures.

ACKNOWLEDGMENT

We wish to thank the households participating in this study along with Meiji Tran and Sarah Towne for their help with water sample collection. In addition, we thank Peter Cable for analyzing the samples. Support for this research was provided by the Robert Wood Johnson Foundation and the UNC IBM Junior Faculty Development Award.

ABSTRACT

The objective of this chapter is to describe the implementation of preventative medical-legal consultations in a NICU follow-up clinic. Preventative medical-legal consultations involve an enhanced neonatal team consisting of a pediatrician, social worker and lawyer working together to assist families of medically complex children access public benefits. We evaluate the success of this program using metrics of parent and child functioning over time. Methods: NICU graduates, as patients at the Center for Healthy Families at the University of Chicago (CHF), were enrolled in the Silver Linings Project after screening when a disconnect between public benefits and developmental and financial needs was identified. At their regularly scheduled pediatrician visits, a legal advocate from the Chicago Medical-Legal Partnership for Children (CMLPC) worked with the medical team during consultation to build an action plan to improve access and utilization of public benefits. Within a year of enrollment, action plans were reviewed, measuring progress on action items in three domains: family items, medical items, and legal items. Results: Twenty-five families participated in this program over 18 months. The physicians, lawyers, and parents completed 80% of total action items across the

* Corresponding Author's Email: Bree.andrews@uchospitals.edu.

sample. Completion of these action items resulted in improved access compared to the time of enrollment in Early Intervention (EI), food benefits (SNAP and WIC) and Individualized Educational Plans (IEP) for children involved. Conclusions: A preventative strategy to reduce social barriers for NICU graduates using a medical-legal consultation and action plan is feasible and effective at improving access to public benefits and decreasing reported parental stress.

INTRODUCTION

Over the last three decades, considerable progress has been made in understanding the harmful effects of poverty and its correlates on family functioning and early childhood development [1–8]. Research also indicates that risk is cumulative: children who experience multiple risk factors (e.g., abuse or trauma), in addition to poverty, are at increased risk for poor outcomes [9, 10]. Significant progress has been made in developing interventions to ameliorate the effects of poverty and other risk factors. Notably, comprehensive and integrated systems of health, educational and social services are viewed as promising strategies to support healthy family functioning, child health and development, and, in turn, adult health and well-being [1, 2, 7, 8, 11–13].

Among the most vulnerable are graduates of the neonatal intensive care unit (NICU), many of whom have complex medical and developmental needs that continue long after they are discharged home. NICU graduates are either premature, very low birth weight (VLBW) infants weighing less than 1,500 grams (3 pounds 5 ounces) at birth, or those born with congenital anomalies (e.g., cardiac) or severe illness (e.g., infectious, hematologic, respiratory) requiring protracted NICU care. Given the significant brain growth during the third trimester of pregnancy, premature birth can have lifelong effects on cognitive, emotional, social and physical functioning [14]. Supported by technology and clinical expertise in the NICU, these tiny infants stabilize and survive at ever-increasing rates, and the birth age at which most infants are viable continues to decline. Because of this medical success, most NICU graduates survive, but they face extensive neuro-developmental and psychosocial needs and are more likely to require specialized health, education, and social services. Indeed, the rate of childhood disability in the United States has been increasing steadily over the past twenty years, due in part to increases in the numbers of low-birth-weight babies and in the survival rate of babies born prematurely [15–17].

Families of NICU graduates must work with multiple entities which have complicated guidelines, restrictive qualifications, and insurmountable bureaucracies to secure much needed services and supports. As a result, many children with complex developmental needs do not receive the therapies, equipment, monetary supports and services that are needed and medically indicated to protect and nurture their health, growth and development. Thus, many NICU graduates from the inner city face social inequities that can demand legal advocacy and action.

Medical Legal Partnerships (MLPs) were created in the last twenty years out of the recognition that there are health inequities and injustices that can be addressed with legal assistance specifically oriented to social determinants of health, and that addressing barriers to social services can have major impacts on outcomes in both medical and social domains. Currently there are 294 MLPs in 41 states. The Chicago Medical Legal Partnership for

Children (CMLPC) was created in 2006 after a research study showed that inner city NICU graduates faced 3-6 unmet legal needs [1, 18, 19]. In particular, the CMLPC facilitates legal care when patients and families are referred from the Center for Healthy Families (CHF), the University of Chicago NICU follow up clinic. The CHF serves 500 children annually, providing primary and developmental care throughout early childhood from 0-6 years of age. Most families who visit the CHF are at or below 200% of the federal poverty level and qualify for income support programs such as Women, Infants and Children Nutrition Program (WIC), social security, Temporary Assistance for Needy Families (TANF), and Supplemental Nutrition Assistance Program (SNAP). The majority (80%) of families are black; about 10% are Hispanic; and about 10% are white.

Figure 1. The cycle of disadvantage and disability as it pertains to VLBW newborns. Dashed lines indicate the processes intercepted by our medical-legal intervention.

At present, medical teams help families identify the factors in their lives (e.g., inadequate developmental and educational resources) that can impact child health, and coordinate a legal referral to CMLPC. In the typical legal referral model, about 5-10 families per year are referred to the CMLPC for legal care, however, these referrals are at critical junctures, when a child is facing a dire health consequence due to inequity in services. A more progressive and effective approach is to identify families early, before crisis occurs to anticipate and prevent adverse outcomes; CHF embarked on this approach the details of which, are presented in this chapter [20].

Recognizing that social and economic factors have a profound effect on the medical care of high risk infants, our objective was to determine when and how to best connect families to legal care in order to maximize access to necessary services and supports, and minimize parental stress. We also aimed to optimize this proactive model for medical-legal intervention, with opportunities for replication in MLPs across the country.

This intervention has implications for demonstrating the value of a more holistic and integrated system of services for VLBW and other NICU graduates to break the cycle of disparities that exist for families living in poverty and facing the medical challenges of fragile children. Figure 1 demonstrates how our intervention attempts to ‘Break the Cycle.’

OUR STUDY

Between January 2016 and June 2017, candidate families were identified from the population of NICU graduates served by the CHF following a review of their clinical records. When there was a seeming gap between the need for public benefits and access to benefits, the family was considered appropriate for the project. Parents were approached to enroll for enhanced legal services within multidisciplinary meetings to build action plans at two key times after NICU discharge:

- Between 4-24 months, children with developmental delays should receive federally mandated, state-provided services such as Early Intervention (EI) and Supplemental Security Income (SSI) benefits. They may also be eligible for ongoing family benefits such as TANF, SNAP and WIC.
- At 36 months, when children should qualify for and receive special education services in public schools based on developmental and educational needs.

Enrollment: Parental consent was obtained at enrollment for the project which included consent for multi-disciplinary meetings in person and by phone, legal care by the CMLPC, assessment of patient data such as medical complexity, evaluation using Warner Initial Developmental Evaluation of Adaptive and Functional Skills [WIDEA-FS] and the Parenting Hassles Index [PHI]), and evaluation of public benefit data including documents from schools and developmental programs.

At the time of enrollment to this project, a medical, family, and legal action plan was created for each family. In the first meeting, legal advocates evaluated eligibility criteria for public benefits and suggested concrete action items for the pediatrician, attorney, and family to complete, with the goal of enrollment in all indicated and eligible social services. For each indicated benefit where gaps in coverage were identified, additional action items were defined for parents, the medical team and the legal team. A document was produced that included contact information for relevant organizations and personnel. Action items for families were written in simple English. Figure 2 outlines enrollment and study flow for the project. Figure 3 is an example of a de-identified action plan from the study.

In addition, follow-up phone discussions and clinic visits were conducted after the initial consultation meetings to 1) assess how families are progressing using the action plan and whether there was any additional need for legal intervention or representation through the medical-legal system; 2) identify perceived and actual bureaucratic “hot spots” that may hinder a family’s ability to continue receiving a particular social or medical support, and 3) to assess and capture the impact of the intervention on parent and child functioning.

Figure 2. Enrollment and study flow among participants.

Measurement Instruments. The Bayley Scales of Infant and Toddler Development, 3rd Edition (“Bayley III”) was used as a baseline measure of development at the time of enrollment. This is a standardized measure of infant development allowing the measurement of infant cognition, language and motor development. Standard Scores have a mean of 100 and a standard deviation of 15. Scores less than 85 are generally considered to be of clinical concern.

Both the WIDEA-FS and the PHI were performed pre- and post-intervention to objectively evaluate the impact of this study on the day-to-day functioning of the participants. The WIDEA-FS is a functional scale evaluating the domains of self-care, mobility, communication and social cognition [21]. It consists of 50 questions and has a maximum score of 200. Higher scores are assigned to children with higher levels of functioning. The scores are scaled for age. Parents respond to statements such as ‘my child holds up [his] arms so I can put a shirt on [him]’ using the schema 1 = Never to 4 = All of the time. The PDH has 20 questions that asks a parent to assess the frequency of a behavior such as ‘my child is a picky eater’ (rarely—constantly) as well as the intensity of that behavior (low---high) [22]. Higher scores indicate a higher likelihood of disruption in parent functioning due to day-to-day hassles.

Every 3-6 months, the action plan was revisited with the family (either by telephone or in person) to assess completion of action items.

This project was approved by the IRB of the University of Chicago Biological Sciences Division. Its assigned IRB number was 15-1262.

FINDINGS

The PI, clinical social worker, and nurse audited 100 patient charts to evaluate gaps in service and legal needs that might be best addressed with legal advocacy and services. 29

families were identified and approached for participation; 25 consented to enrollment in the project.

80% of infants enrolled were born extremely low birth weight (ELBW = less than 1,000 grams) or very low birth weight (VLBW = less than 1,500 grams), and had early developmental or school needs evaluated by the CMLPC. 20% had delays associated with other NICU morbidities (two children with neural tube defects, one who had required extracorporeal membranous oxygenation, and one diagnosed with a primary genetic condition) and were also referred. Table 1 outlines basic demographics of the study participants.

At the start of the project, the Bayley III Scores and WIDEA-FS scores were at least one standard deviation below average for age equivalency, demonstrating marked developmental and functional needs across our sample. The PDH scores were higher than normal for all enrollees for both the frequency and intensity of child behaviors, indicating the chronic difficulty parents had in caring for their children with impairments. The average number of action items identified by the action plan was 6 per family.

At completion of the project, the WIDEA-FS scores were on average 15 points higher and parenting hassles scores were slightly improved on average by five points, for participating families. Most importantly, 80% of action items had resolution upon follow up with families at the end of the study. Table 2 shows the enrollment and post-intervention results.

Table 1. Patient demographics

Patient Population:	Pre-Term Infants (n = 21)	Term Infants (n = 4)
Mean NICU Length of Stay:	100 days	60 days
Mean Birth Weight:	820 grams	2650 grams
Mean GA (weeks):	26 wks ± 1.7 wks	36 wks ± 2.5 wks
Male: Female	13:8	3:1
Mean age at enrollment:	3.3 yrs/39 months	2.4 yrs/29 months

Table 2. Developmental and parenting stress metrics at enrollment and follow-up

Evaluation (mean +/- 1SD)	Enrollment (n = 25)	6-12 months after enrollment
Bayley III		
Cognitive	70 +/- 12	n/a
Motor	76 +/- 14	
Language	84 +/- 13	
WIDEA-FS score	125+/-11	140+/- 15
PDH Scores		
Frequency	50+/-10	45 +/-8
Intensity	70+/-15	65 +/-10
Action Items (identified/remain)	6+/- 2	2+/-1

In the qualitative interviews with parents, the overarching themes that parents voiced were enthusiasm for having ‘doctors and lawyers located in the same office’ and ‘working together’ to help obtain the best services for their children. Of the eight families interviewed,

all stated that having more ‘written’ and ‘correct’ information about their services on the action plan was helpful. A family who had a lawyer attend an IEP meeting stated, “the school behaved differently when I had a lawyer with me, the IEP was enhanced, and I felt better knowing I had done everything right to help him in school.”

Of note, six families required direct representation by a legal advocate regarding a conflict with the public school system. In these six cases, a lawyer provided representation to assist in appropriately revising the student Individualized Educational Plans. Legal advocacy with use of preventative legal advocacy and service per family ameliorated the need for direct representation in the remaining 19 families.

DISCUSSION

Although graduation from the NICU represents a major medical and emotional accomplishment, NICU graduates face early childhood challenges, especially in terms of access to developmental and social services. Although comprehensive medical care with a medical home is essential, additional social, therapeutic and educational services do have a positive impact on the graduates. Although the CMLPC has provided consultation and legal services to the patients at the University of Chicago for 10 years, in this project, we implemented a broader proactive framework, by using an action plan to better describe and delineate the medical, legal and family action items that would enhance services for the child and family.

Implementation of the medico-legal intervention before discharge and the organization and codification of the action plan resolved 80% of action items, far surpassing initial expectations of this project. Although many of the action items defined were simple, such as making a phone call to a service agency or obtaining a document, others were more complex and required intervention by the pediatrician, attorney or another professional such as a social worker, nurse, or paralegal.

Parents reported slightly better functioning of their children over time and experienced fewer parenting ‘hassles,’ as compared to the time of enrollment, although a control group was not measured for comparison over time. Qualitative feedback from parents indicated that the coordinated nature of this project with a defined action plan was a welcome and valuable intervention.

When we designed the intervention, we anticipated that families would need preventative legal care at two time-points corresponding to the enrollment windows for social and educational resources (4-24 months and 36 months, respectively). We found that most families facing barriers to public benefits identified their needs at later stages than anticipated. The four families approached who did not consent to our study all had infants who were 24 months or younger. It appears that families may be able to navigate public benefits adequately when they are in the immediate wake of NICU discharge but that this process becomes more challenging with time.

There are some limitations in the current study. As mentioned above, a control group was not measured for comparison and some changes from baseline may be related to the natural course of the child’s development. Because of the short time frame, we do not have ongoing information about Early Intervention or school attendance with appropriate IEP services or

about the maintenance of public benefits after the study. In addition, we were not able to obtain Bayley III scores within 6-12 months after enrollment, making it difficult to follow developmental progress over time. However, these children will be followed with appropriate developmental testing in the next 6 months to further document the impact of this study.

Silver Linings Action Plan

Figure 3. Sample medical-legal action plan.

CONCLUSION

Families of NICU graduates face complex medical and social needs often requiring interaction with many government agencies. Although formal legal representation may not always be necessary or practical, the medical and legal action plan we developed can be viewed as being similar to the Asthma Action Plan that is widely used and considered a marker of quality and adherence in pediatric practice [23]. Having a physical document articulating the action plan that can be referenced by families, with key phone numbers and collective goals, can be helpful in improving interdisciplinary connectedness and the receipt of public benefits indicated for infants and children with complex needs and their families. The implementation of medical-legal action plans was feasible and efficacious in terms of improving parent and child functioning and parent satisfaction for low income families in an inner city NICU follow-up clinic.

Chapter 264

EXPLORING THE ROLE OF SOCIAL SUPPORT IN UNDERSTANDING BARRIERS TO BREASTFEEDING PRACTICES FOR ADOLESCENT MOTHERS

***Colleen Clark^{*}, MPH Candidate
and Kimberly Price[†], PhD, MCHES***

Center for Graduate Studies of Asheville,
Program of Public Health, Lenoir-Rhyne University,
Asheville, North Carolina, USA

ABSTRACT

Although breastfeeding has many nutritional, immunological, and positive health outcomes for both mother and infant, the prevalence of breastfeeding among adolescent mothers is low. Understanding the needs of this vulnerable population and the obstacles they face could assist in the development of health promotion strategies and lead to greater participation in breastfeeding practices. The purpose of this chapter was to understand the role of social support in adolescent mother's breastfeeding practices. Adolescent mothers were recruited at community agencies that implement a North Carolina Health and Human Services funded Adolescent Parenting Program (APP). The project focuses on breastfeeding experiences of APP participants in Western North Carolina, part of the Southern Appalachian region. Participants completed a self-report survey regarding their breastfeeding experiences. Of the 16 participants, most (87.5%) attended a prenatal class where breastfeeding was discussed and most (75%) initiated breastfeeding their infants, while only 12.5% sustained a breastfeeding practice past 4 months. Few felt comfortable breastfeeding at work (31%) or at school (43.8%). All mothers had a healthcare provider or someone at the hospital speak to them about breastfeeding. Perceptions of social support were gathered using the ESSI instrument, validated in cardiac patients. Mothers reported that they had "someone available" to them who showed them "love and affection" ($M = 4.625$ on 5 point scale). A mother's

[†] Corresponding Author's Email: kimberly.price@lr.edu.

interpersonal relationship with her healthcare provider, family, and peers can help cultivate empowerment in order for her to navigate the challenges of breastfeeding and directly improve the long-term health outcomes for both the mother and child.

INTRODUCTION

Despite the nutritional, immunological, and positive health outcomes breast milk offers for mother and infant, the prevalence of breastfeeding among adolescent mothers is low. Understanding the specific needs of this vulnerable population and the obstacles they face could help develop effective health promotion strategies and lead to greater participation in breastfeeding practices. Compared to mothers twenty years or older, rates of adolescent breastfeeding for eight weeks or longer is 40% lower [1]. While breastfeeding initiation practices have been increasing about 2% per year since the new millennium, adolescent mothers' practices remain low or underreported [1]. Lack of breastfeeding can be a major public health concern as benefits for both mother and baby are striking.

Benefits of Breastfeeding

There are many benefits of breastfeeding for both mother and infant [2, 3]. Breast milk contains essential nutrients needed for an infant's growth. Colostrum, a thick yellow substance secreted at the beginning of lactation, is high in carbohydrates, proteins, and antibodies [4]. The nutrients in human milk are specific to the needs of the human infant. Human milk is easy for the infant to digest, more bioavailable, and provides immunological benefits that an infant can only obtain by receiving human specific milk [5].

Breastmilk has been shown to reduce the risk of gastrointestinal infections, respiratory infections, otitis media, serious cold and throat infections, and sudden infant death syndrome (SIDS) [2]. The protective nature of breastmilk against SIDS has incited recommendations to include breastfeeding in risk reduction messages [6]. In cases of extreme prematurity, an exclusive breastmilk diet can significantly reduce the risk and subsequent complications of necrotizing enterocolitis, which can be life-threatening [7, 8]. Physical health benefits of breastfeeding continue through a child's life. Breastfed babies have lower rates of celiac disease, inflammatory bowel disease, adult obesity, type 1 diabetes, type 2 diabetes and childhood leukemia [2]. A 2017 study by Ahmadizar et al [9] found that within a pediatric population with asthma, increased duration of breastfeeding decreases the number of asthma exacerbations.

Mothers also experience physical benefits of breastfeeding. Godfrey and Lawrence [10] found mothers who breastfeed two years or more have a decreased risk of heart disease and type 2 diabetes. Breastfeeding mothers have a decreased incidence of postpartum depression [10, 11]. Enhanced infant bonding through skin to skin contact between mother and infant during breastfeeding increases endogenous oxytocin, a neurohormone that induces milk release. Oxytocin levels have been shown to positively affect maternal attachment behaviors [12]. A mother's touch, gaze, vocal, and facial expressions that occur during breastfeeding are important physiological processes of attachment [13]. Breastfeeding can be seen as essential

in creating healthy life outcomes for both mother and baby physically, socially and emotionally.

In 2012, the American Academy of Pediatrics (AAP) stated that maximal benefits of breastmilk are reached when mothers follow the recommended six month sustained breastfeeding practice that is followed by a year of continued breastfeeding [2]. Healthy People 2020 highlights the importance of breastfeeding by setting six-month breastfeeding goals to 60.6 percent from 43.5 percent and to increase the proportion of breastfeeding at one year to 34.1 percent from 22.7 percent [3]. Understanding adolescent mothers' barriers while examining possible ways to increase social support can help this population reach the recommended breastfeeding duration and full benefits of breastmilk.

Adolescent Mothers' Breastfeeding Barriers

Multiple individual, practical, cultural, social and economic factors may keep adolescent mothers from breastfeeding. Though some obstacles such as physical barriers or general breastfeeding stigmas may be of concern to all mothers, adolescent mothers face unique roles and challenges that may disrupt their success. Social support systems play an essential role to an adolescent mother's empowerment and breastfeeding practice [14, 15]. Levels of social support from co-workers (or fellow students), family members, significant others, peers, and healthcare professionals can serve as a barrier, if low, or an advantage if high [14].

Adolescent mothers, like their adult counterparts, often are juggling multiple roles as a new mother. However, compared to their older counterparts, adolescent mothers are more likely to be lower income and lack access to educational opportunities [14, 15]. Tucker et al. [14] found that almost half of new adolescent mothers identified returning to school as one of the reasons for not initiating breastfeeding and more than a third included this as one of the reasons they stopped breastfeeding. Support from schools and workplaces that have resources, such as nursing rooms, can create a positive breastfeeding culture for new mothers [16]. In the state of Illinois, new legislation was passed in August 2017 requiring all public and charter schools to provide students with a place to lactate and store pumped milk. In addition, the law states adolescent mothers cannot be subject to academic penalty for using the nursing room and that they must receive academic accommodations. Policies for adolescent mothers within a school setting send a message of support that has the potential to decrease stigma among peers.

Peer acceptance and support significantly influences breastfeeding practices. Adolescent mothers cite that some peers offer more negative outlooks on breastfeeding through little understanding of breastfeeding or their own personal difficulty with breastfeeding [14, 15]. Conversely, when teens encounter positive peer or family modeling they are often motivated to continue breastfeeding [15]. Support from family during school hours can be essential. Family members who are willing to bring the infant to the mother is a practical necessity while also demonstrating support for importance of the breastfeeding practice [15]. Tucker et al. [14] found that when participants had female family members who were encouraging, adolescent mothers consistently breastfed two months or longer.

Some of the practical barriers that inhibit adolescent mothers from continuing breastfeeding are similar to older mothers. These physical obstacles include difficulty with correct attachment to the breast, concerns about the infant getting enough milk, and feelings

of pain and discomfort [14, 15]. Prompt management of these common concerns in the early post-partum period is associated with increased duration of breastfeeding. Like all mothers, adolescent mothers need proper technical guidance when latching the baby to the breast, education regarding feeding cues, proper voids and stools and prevention and management of sore nipples.

Healthcare workers play an essential role in helping adolescent mothers cultivate empowerment through better understanding of breastmilk's benefits [14]. Lower breastfeeding rates were found to be significant in adolescents who had no prenatal healthcare provider, or who were absent from prenatal classes [17]. Gaining breastfeeding knowledge and setting intention are crucial and an estimated 60% of mothers who intended to breastfeed sustained a longer practice [17]. Cultivating empowerment through word choice can improve outcomes. Statements that focus on the mother and what she can personally do for her baby are more effective. One breastfeeding teen stated that breastfeeding: "Was very important because the first milk is something that can help jumpstart your baby's brain" [14]. It is important for healthcare workers to provide consistent information when advocating and supporting breastfeeding. Additionally, many mothers find it hard to access outpatient professional assistance when needed [14]. Lack of technical guidance from their providers or access to lactation specialists can discourage mothers from continuing breastfeeding.

Different sociological factors can also determine a mother's ability to sustain a breastfeeding practice. Lack of social support, the demands of work/school, and access to breastfeeding knowledge are some of the many obstacles that have been found to make breastfeeding difficult for adolescent mothers.

In North Carolina obstacles to adolescent mothers' breastfeeding practices have been recognized by the North Carolina Department of Health and Human Services. This department funds selected local health departments, organizations, and public schools that wish to implement an Adolescent Parenting Program (APP) in their community. The goal of these programs is to provide support while creating a positive peer community amongst adolescent mothers. Aims for the program include increasing maternal self-sufficiency, decreasing second pregnancies, and increasing high school graduation rates. The aims for the children of APP participants include increasing cognitive development, establishment of a medical home, and the creation of a safe home environment. Breastfeeding can be an essential way for the program to help meet their goals. The purpose of this study was to gauge current breastfeeding practices among this population and identify the influences social supports have on the breastfeeding practices.

In reviewing the literature, no published studies examining cumulative adolescent mothers' attitudes, practices, and social support in rural Western North Carolina (WNC) were found. Smith et al. [15] used qualitative methods to look at the role of social support of adolescent mothers in urban, Greensboro, NC while Tucker et al. [14] used PRAMS to look at adolescent mother's feeding practices in North Carolina. No research to date has looked at breastfeeding practices among APP participants.

OUR STUDY

Participants of four Western North Carolina APP agencies were contacted for recruitment. The agencies are located in four different Western NC counties (Buncombe, Catawba, Henderson, and Caldwell). A survey was developed to gain insight into breastfeeding behaviors in our study location. A non-experimental cross-sectional study design was used to assess the knowledge, attitude, current practice of breastfeeding, and perceptions of social support. Adolescent mothers who participated in programs held within community organizations in Western NC were recruited to participate in this anonymous, confidential survey. The target population was adolescent mothers, ages 16-21 years old. This study was approved by the Institutional Review Board of Lenoir-Rhyne University.

The survey collected self-reported data, to be completed in a single 15-minute time period (Appendix A). Most questions regarding mothers' experiences (with prenatal classes, feeding practices, potential obstacles, healthcare services, and social support) required a yes/no response. The social support survey items were adapted from the ENRICH Social Support Instrument (ESSI) which was validated in cardiac patients [18]. The ESSI gauges social support through open ended or Likert scale questions. Social media questions were included to gauge interest in using this platform for connecting with other mothers and educational purposes.

Table 1. Adolescent mothers in Western North Carolina Adult Parenting Programs: Demographics

Demographics	<i>n</i>	%
Age

13-18	3	18.8
19-24	4	25.0
>24	2	12.6

The adolescents were recruited through local agencies and distributing surveys at organizational events. The survey was distributed by the principal investigator or the director of the program on dates that were convenient for the agencies due to planned organizational events. At the beginning of each event, mothers were informed of the study, educated about potential risks and benefits to participation and then invited to participate. Although this

research included minors, it was verified by the IRB that an informed consent from the adolescent mothers' parents was not needed. After informed consent was obtained, selection criteria were verified, and the surveys were distributed. In order to maintain anonymity, the signed informed consent form was collected and saved in a letter envelope separately from the anonymous survey. SPSS was used to analyze the results.

FINDINGS

Participation rates for completing the survey was 100% among the 16 mothers who met selection criteria and consented to participate. This study was self-selecting. The participants ranged in age from 16 to 19 years old. The participants identified as White (56.3%), Black (12.5%) or Hispanic (25%). A majority had children aged two years or younger (87.4%) (see Table 1).

Most mothers (87.5%) attended a prenatal class with breastfeeding instruction. The majority (81.3%) reported an intention to breastfeed, with more than 40% indicating breastfeeding was "very important." A common theme stated by the participants about breastfeeding was that it is "healthier", gives "nutrition [nutrients, nutritious]," and "breast is best." The majority of the mothers initiated breastfeeding (60%) but only 12.5% sustained the practice past four months. Many participants reported using formula (87.5%) for an average of 8.3 months and 56.3% of mothers attempted combined formula/breastfeeding. Many (62.5%) reported experiencing pain and 43.8% reported the pain affected their decision to breastfeed. When the participants were asked specifically why they chose either breastmilk or formula, they cited not producing enough milk (43.8%), nipple pain (12.5%), and difficulty latching (6.25%) as the reasons they chose formula. Mothers often described their feeding decision by first stating, "I tried" or "I really wanted to" breastfeed, but started to use formula because of a physical barrier. One of the adolescent mothers who sustained an 18-month practice reported, "I thought that breastfeeding was a better choice for both my son and I."

Out of the 81.8% that answered work related questions, only 25% reported having a place to pump their breastmilk at work. Only 31% reported that they would feel comfortable pumping at work. In the same vein, 62.5% reported having a place to pump at their high school but only 43.8% admitted to being comfortable doing so. 56.3% of the respondents reported being breastfed as a child and 37.5% knew that their mothers were breastfed when they were infants (see Table 2).

All mothers had a healthcare provider or someone at the hospital speak to them about breastfeeding, and most (81.3%) received outpatient services regarding breastfeeding feeding concerns. Few mothers (31.3%) reported receiving encouragement to breastfeed from the father of the child, but many received encouragement from family (75%) or friends (68.8%). In all, most (87.5%) felt supported in their feeding choices (see Table 3a).

Using the ESSi five-point Likert scale, mothers reported how often they felt supported (higher scores indicating greater support). Of the six items rated, mothers most frequently reported that they had "someone available" to them who showed them "love and affection" ($M = 4.625$). Social support scores are described in Table 3b.

Adolescent mothers reported using social media such as Instagram, Facebook, Snapchat, and Youtube for educational purposes (87.5%) and as a way to connect with other mothers

(100%). Many (62.5%) were interested in creating a breastfeeding website for young mothers as displayed in Table 4.

Table 2. Adolescent mothers' experiences of breastfeeding

Adolescent mothers' experiences		<i>n</i>	%
Attended a prenatal class with breastfeeding education		14	87.5
Planned to breastfeed		13	81.3
Importance of breastfeeding			
Not important		0	00.0
Somewhat important		4	25.1

Use of social media for educational purposes	14	87.5
Use of social media to connect with other mothers	16	100
Interested in creating a breastfeeding website	10	62.5

DISCUSSION

This preliminary study surveyed 16 adolescent mothers to better understand their beliefs, behaviors, and barriers that may either encourage or hinder them from breastfeeding practices. Although a majority of the mothers (81.3%) intended on breastfeeding and all (100%) deemed breastfeeding “somewhat” to “very” important, only 75% initiated breastfeeding their babies and only two mothers (12.5%) surpassed the 6-month goal set by Healthy People 2020 [2]. Though initiation rates were higher in this population (75%) than the national average of a little over 50%, the rate of breastfeeding past 6 months was lower than the national average of 19% [1, 14]. It is encouraging that adolescent mothers in this population initiated breastfeeding, which may, in part, be due to the participation in an Adolescent Parenting Program. Nevertheless, greater support, specifically technical breastfeeding support, can help adolescent mothers in this population achieve their intention and the optimal 6-month goal.

Best practices for adolescent mothers to sustain breastfeeding can be ascertained through the use of the socioecological model. This behavioral model describes effective health promotion as a synergistic effort between five different levels: the individual, interpersonal relationships, organizations, communities, and society. Much like the ecology of the natural world, each level depends on each other for change. For example, Illinois’ state breastfeeding legislation supports an adolescent mother’s breastfeeding practice in school and this influences adolescents in a positive, supportive manner. An adolescent mother’s immediate environment is influenced by the many interpersonal conversations she encounters as she connects with and learns through her inner trusted circle. For example, the possibility of pumping during the day in a safe environment may not only support and teach the mother during lactation, but also influences peers, family members, and healthcare providers who interact with others experiencing similar issues.

Results from this study indicate that some women are uncomfortable pumping/expressing their milk at work or at school. Assessing the availability of time for a mother to pump without penalty at work or school may be a better indicator for breastfeeding success

than access to a breast pump. To help overcome this barrier, schools and worksites should be required to offer an on-site nursing room to ensure privacy and cultivate peer support.

The mothers in this study were specific to the Adolescent Parenting Program. At the core, programs like the APP help adolescent mothers navigate and utilize resources to optimize health and personal growth for mother and baby. Organizational support and interpersonal connections with other adolescent mothers is an important service the program provides. This may explain the high, positive report of social support from these mothers. Although only a third of these mothers received encouragement to breastfeed from the father of the child, the rate of encouragement from family and friends was high. High rates of initiation and perceived importance of breastfeeding among this population may be due to participation and peer support from the APP. Nevertheless, consistent with previous literature, technical breastfeeding support is deeply important and not always included in programs where social support is given [14].

According to Tucker, Wilson and Samandari [14], adolescent mothers can be inhibited from continuing to breastfeed due to practical difficulties, e.g., from improper infant latch, concerns about the infant getting enough milk, or pain and discomfort. At least one of these reasons was echoed by 62.5% of the participating mothers of this study as the main reasons for choosing formula. Healthcare providers and lactation outpatient services are an important source of technical information to overcome some of the initial hurdles of breastfeeding. Interestingly, 81.3 % of the participating mothers received outpatient education but only 43.8% were offered a breast pump. There seem to be gaps in outpatient education that may result in breastfeeding discontinuation. Research focusing on the adolescent mothers' technical conversations with healthcare providers may provide insight to this finding. In addition, eliciting the technical breastfeeding knowledge of peers and family members may help adolescent mothers anticipate potential complications and empower mothers to better utilize their healthcare providers. The APP may be able to increase their participant's breastfeeding rates by opening discussion on common pitfalls as well as to the benefits of breastmilk.

In addition to feeling supported in their breastfeeding decisions, it is important that adolescent mothers receive ongoing social support for breastfeeding practices [19, 20]. Health outcomes and healthy behaviors are improved when people perceive they are supported in their lives, at home, online, at work, or at school [18].

Smartphones play an important role in adolescent communication. Health initiatives such as the adolescent suicide prevention hotline Crisis Text Line and the adolescent smoking cessation program SmokeFreeTeen recognize this importance and utilize smartphones to reach the adolescent population. Questions on this survey regarding social media use and participant interest in an adolescent mother group were designed with quick access to social support and education in mind. The perception of social support through the use of social media may be influential since most adolescents use popular sites as ways to connect with one another and obtain information.

While many North Carolina initiatives focus on reducing teen pregnancy and teen birth rates [21], adolescent parenting programs can have an impact on the quality of mothering practices by providing social support and addressing barriers that impede new mothers in breastfeeding initiation. Since breastmilk has numerous benefits over formula feeding [2, 4, 5, 22], the emphasis can shift toward supporting and educating adolescent mothers in order to "break the cycle" of health disparities (see Figure 1). Breastfeeding is an affordable and

sustainable quality source of nutrition for the baby that improves long term health outcomes and decreases unwanted health risks. The process of breastfeeding improves maternal and infant health and naturally increases maternal child bonding. By focusing on social support and breastfeeding education together, adolescent mothers will be equipped for breastfeeding success which directly improve the long-term health outcomes for both the mother and child.

CONCLUSION

There were many limitations of this study which can provide insight on future opportunities for research within this population. This population was self-selecting which may affect the outcome of this data. The participating adolescent mothers may have been more willing to communicate their experiences which may present bias to the results. Though the APP is required to have thirty participants at each event, the actual attendance was low at the time of enrollment. Many of the adolescents work and depend on unreliable transportation which may limit attendance. Perhaps in the future, an online survey may reach participants and yield a better sample.

Detailed examination of agency and institutional breastfeeding programs may better inform future directions for this research. A broader qualitative study design may help explain the high initiation rates followed by low continuation rates among adolescent mothers. Demographic information such as income, access to transportation, parity, and marriage information may have also been fruitful.

Chapter 265

A COMMUNITY-BASED PROGRAM TO DECREASE THE RISK OF CHILDHOOD OBESITY

ABSTRACT

In the United States 80% of obese adolescents, 50% of obese preschool-aged children, and 50% of school-aged children are prone to develop adult obesity. Health education and physical activity for children at risk for obesity are key to mitigating the risk of developing obesity as an adult. Health education and physical activity complement each other, improving children's behaviors and attitudes towards health. This study builds upon an existing body of knowledge about the prevention of obesity and long-term morbidity among rural youth from disadvantage backgrounds. The purpose of this study was to improve the attitudes and behaviors towards healthy eating through combining health education and physical activity among children of Macon County, Alabama. We conducted a mixed method design with a cluster sample of 11 participants. We used a pre/posttest lifestyle student created questionnaire guided by the Institut de Recherches Cliniques de Montréal (IRCM) lifestyle questionnaire and the Simple Lifestyle Indicator Questionnaire to characterize health behaviors (i.e., consumed vegetables, fruits, sweet drinks and water) and attitudes (i.e., enjoyment of exercise, emotional eating, ways of staying active when the weather is bad). Our study concluded that an interactive health education and physical activity interventions positively influenced healthy eating behaviors and attitudes in nine out of eleven participants for attitudes and six out of eleven participants for behaviors on healthy eating.

INTRODUCTION

The prevalence of childhood obesity in the United States (US) tripled in the 1980s and 1990s, earning the recognition of being the most common chronic childhood disorder [1]. The prevalence of obesity among US children and adolescent's ages 2-19 year is approximately 17% [2], but obesity prevalence varies across different ethnicities. According to the National Health and Nutrition Examination Survey (2015-2016) there is an 8.9% difference between obesity in African Americans compared to non-Hispanic white youth [3]. There are several diseases and disorders that obese children can develop. These include high blood pressure, dyslipidemia, metabolic syndrome, obstructive sleep apnea and other breathing problems, osteoarthritis, anxiety, depression, and low self-esteem [1].

A child's diet plays a major role in obesity. Children ages 6-18 years are more likely to consume foods from fast food restaurants which is one of the causes of overweight and obesity [4]. A study conducted by Choi et al [5] investigating the attitude and behaviors towards nutrition and diet of elementary school children concluded that, for the improvement of nutrition knowledge, education about nutrition attitudes and dietary behaviors is required [5]. Roe et al., [6] investigated health promotion interventions (health education, nutrition, and dietary change strategies) in community settings, and concluded that the greatest changes in dietary behaviors were seen in studies with highly motivated volunteers in intensive health education programs [6]. A study by Shariff et al., [7] showed that a nutrition education program compared to a health and physical education curriculum has a greater impact on changing the knowledge, attitudes, and practices of primary school children towards healthy nutrition; the study used the "fun while learning" concept engaging with the participants through group discussions on nutrition topics, demonstrations, nutrition contests, workbook assignments, and singing sessions to keep their attention as opposed to using the traditional classroom style teaching method [7]. Mealtime has been demonstrated to be a time for adults to promote healthy eating habits with children [8]. Children who eat at least three meals per week with family are more likely to eat breakfast regularly and have increased intake of fruits and vegetables which is beneficial for health and nutrition [1].

Figure 1. Break the cycle diagram.

Sedentary lifestyles and poor dietary habits increase prevalence of obesity-related comorbidities [9]. Physical activity has an important role in the treatment of obese and overweight children [10]. According to Lazaar [11], increasing physical activity or exercise is one of the cornerstones in treating pediatric obesity. A meta-analysis addressing the effects of physical activity (strength training and aerobic) for seven weeks, 2-5 times per week, 10-60 minutes in treatment of obese and overweight children, concluded that physical activity reduces body fat in obese and overweight children and adolescents [10]. A moderate amount of physical activity for at risk children can provide substantial health benefits. According to the Centers for Disease Control and Prevention (CDC), children and adolescents should engage in 60 minutes a day of moderate- (3.0 to 6.0 METs; 3.5 to 7 kcal/min) or vigorous- (> 6.0 METs; more than 7 kcal/min) aerobic physical activity [12].

This study implements a combined physical activity and health education intervention to increase healthy eating behaviors and attitudes in African American children residing in Macon County, Alabama. Our study was informed by the cycle of environmental health disparities ecological framework created by the Southeast Pediatric Environmental Health Specialty Unit (PESHU) in Atlanta, Georgia (see figure 1). This model includes compound risk factors (i.e., limited educational services), personal characteristics (i.e., limited education), environmental characteristic (limited access to healthy food), and health characteristics (obesity) that can lead to serious adverse health effects when children transition into adulthood if they remain obese [13].

OUR STUDY

To better understand the potential effects of physical activity and nutrition education on behaviors of children in Tuskegee, Alabama, we used both quantitative and qualitative designs. The study was approved by the Institutional Review Board at Tuskegee University. The City of Tuskegee is located in Macon County (rural Alabama). According to the Data USA 2015, the population of Tuskegee is 9,218 and 20,018 for Macon County [14, 15]. Macon County is among the 18 Black Belt counties of Alabama.

Our study focused on three components that contribute to obesity: limited access to healthy foods, limited health education, and limited community physical activity accessibility. The 2014 preschool obesity rates in Macon County and Tuskegee, are 17.3% and 31.7% respectively [16]. Macon County is a food desert which is defined as an “area in which it is difficult to gain access to or buy affordable, good quality food” [17]. Some residents in Macon County reside approximately 20-25 miles away from grocery store where there is affordable, good quality food. As of 2014 the percentage of individuals consuming a healthy diet in Macon County and Tuskegee, Alabama is 50.2% and 48.2% respectively [16]. We have no formal information on programs that target health education and physical activity combined in Tuskegee, Alabama.

PARTICIPANTS AND MEASUREMENT

The study used cluster sampling to recruit children between the ages of 6-14 years with six girls and five boys. We recruited 11 African American children from disadvantaged backgrounds, living in Tuskegee, Alabama. All were participants in the Tuskegee Youth Safe Haven Program, which is an afterschool program for youth 6-18 years old located in Macon County, serving economically disadvantaged neighborhoods [18]. The program provides services to improve living conditions of its participants and provide pre-professional youth development resources for youth in Macon County. Informed consent (voluntary agreement of the guardians for the participants to participate in research) was obtained from parents. Informed assent (willingness to participate in the research from youth under 18 years) was obtained from the children.

Table 1. Student Created Lifestyle Questionnaire guided by the IRCM healthy lifestyle and the Simple Lifestyle Indicator Questionnaire (19, 20)

Questionnaire	A	B	C
How many meals do you eat a day?	1-2 meals a day	3 meals a day	4 or meals a day
How many veggies do you eat?	Less than 1 a day	2-3 a day	More than 4 a day
How many fruits do you eat?	Less than 1 a day	2-3 a day	More than 4 a day
How often do you eat sweet foods? (candies, chocolate, table sugar, honey, jam)	3 times a week or less	4-5 times a week	Every day
Do you drink sweet drinks? (Fruit juice or fruit drinks, soft drinks or energizing drinks, iced tea, lemonade)	1 cup a day	1-2 cups a day	2 or more cups a day
How many cups of water do you drink a day?	1 cup a day	1-2 cups a day	2 or more cups a day
How often do you walk or ride a bike?	1-2 times a week	More than 3 times a week	Most of the time
How many times a week do you move around for at least 30 minutes?	Never	2-3 times a week	4-6 times a week
Do you like working out?	A lot	A little	Not at all
Do you find different ways to exercise when it's raining and you don't want to go outside to exercise?	Never	Sometimes	Always
Do you drink enough during and/or after a training session?	Never	Sometimes	Always
I am in school for long hours and when I get the chance to relax, I just want to sit in front of the TV.	Never	Sometimes	Always
What I eat now is not going to make a difference for my health.	Never	Sometimes	Always
When I eat chips or cookies, I have to eat the whole bag.	Never	Sometimes	Always
I eat a lot when I am happy, sad, angry.	Never	Sometimes	Always
I easily feel upset.	Never	Sometimes	Always

The 11 participants were administered a modified questionnaire guided by the Institut de Recherches Cliniques de Montréal (IRCM) lifestyle questionnaire and the Simple Lifestyle Indicator Questionnaire [19, 20] consisting of two sections; behaviors and attitudes of healthy eating (see table 1). Participants engaged in one hour of health education and one hour of

physical activity once a week over 18 weeks from September 2016 to February 2017 for a total of 18 sessions. The modified lifestyle questionnaire was used as a pre/post-test method with details pertaining to behaviors and attitudes towards health (i.e., meals consumed a day, intake of water, engagement in exercise, and enjoyment of exercises) [19, 20]. Participants wore pedometers during the physical activity intervention to provide information on the number of steps taken. During the health education intervention, the study children met in classroom settings, used visual aids, used worksheets on balanced meals, gardening using fruits and vegetables, and prepared and consumed vegetables, and fruit ‘smoothies’ provided by the local food bank. Educational sessions were interactive; the children worked in groups and presented to each other their worksheets or posters at the end of the health education intervention. During physical education, the children engaged in kickball, relay racing, sack racing, bean bag toss, football, basketball, and a simulated jeopardy game. All activities physical activities were outdoor and limited to three games a session.

FINDINGS

Figures 2 and 3 present the results of the differences in average scores from the pretest and posttest for the student created lifestyle questionnaire guided by the IRCM lifestyle questionnaire and the Simple Lifestyle Indicator Questionnaire.

Overall the results from pretest to posttest were as follows: 45% of the participant’s behaviors towards healthy eating increased, 65% of the participant’s attitudes towards healthy eating increased, 27% of the participants had no change in behaviors towards healthy eating and 0.09% of the participants had no change in attitudes towards healthy eating. 28% of the participants had a decrease in behaviors towards healthy eating and 34.9% of the participants had a decrease in attitudes towards healthy eating.

Figure 2. Average scores of the Lifestyle Questionnaire Pretest and Posttest of Behaviors on Healthy Eating.

After 18 sessions of intervention, results from the posttest on behaviors of healthy eating revealed that 82% of the children eat three meals a day (18% increase from pretest score

64%), 55% of the children consumed two-three vegetables a day (19% increase from pretest score 36%), 45% eat sweets every day (19% decrease from pretest score of 64%), 73% of the children drink one-two cups of sweet drinks a day (18% increase from the pretest score 55%), 64% drink one-two cups of water a day (28% from pretest score 36%), 55% of children walk or bicycle most of the time (9% decrease from the pretest score of 64%) and 91% engage in exercise for at least 30 minutes for four-six times a week (18% increase from the pretest score 73%) (see table 2.)

Figure 3. Average scores of Lifestyle Questionnaire Pretest and Posttest of Attitudes on Healthy Eating.

Table 2. Behaviors of healthy eating

	Pretest	Posttest	Pretest	Posttest	Pretest	Posttest
	1-2 meals a day (A)		3 meals a day (B)		4 or meals a day(C)	
1. How many meals do you eat a day?	36%	18%	64%	82%	0%	0%
	Less than 1 a day		2-3 a day		More than 4 a day	
2. How many veggies do you eat?	55%	27%	36%	55%	9%	18%
3. How many fruits do you eat?	45%	36%	36%	45%	18%	18%
	3 times a week or less		4-5 times a week		Every day	
4. How often do you eat sweet foods? (candies, chocolate, table sugar, honey, jam)	27%	18%	9%	36%	64%	45%
	1 cup a day		1-2 cups a day		2 or more cups a day	
5. Do you drink sweet drinks? (Fruit juice or fruit drinks, soft drinks or energizing drinks, iced tea, lemonade)	18%	0%	55%	73%	27%	27%
	1 cup a day		1-2 cups a day		2 or more cups a day	
6. How many cups of water do you drink a day?	36%	18%	36%	64%	27%	18%
	1-2 times a week		More than 3 times a week		Most of the time	
7. How often do you walk or ride a bike?	27%	18%	9%	27%	64%	55%
	Never		2-3 times a week		4-6 times a week	
8. How many times a week do you move around for at least 30 minutes?	0%	0%	27%	9%	73%	91%

At the completion of 18 sessions of intervention, the significant results from the posttest on attitudes of healthy eating concluded that 82% of the children do not like working out (18% increase from the pretest score 64%), 82% of the children always find different ways of staying active when the weather is bad (73% increase from pretest score of 9%), 55% of the children always drink water after exercising (28% increase from pretest score 27%), 64% of the children sometimes watch TV after long hours at school (9% increase from pretest score 55%), 73% of children believe being careful now will not make a difference with their health (37% increase from pretest score 36%), 45% of the children eat chips and cookies (9% increase from pretest score 36%), 82% of the children never eat due to emotional upset (no change from pre-posttest score) and 73% of the children sometimes feel easily upset (9% increase from pretest score 64%) (see table 3).

Table 3. Attitudes of healthy eating

	Pretest	Posttest	Pretest	Posttest	Pretest	Posttest
	A lot(A)		A little (B)		Not at all (C)	
1. Do you like working out?	0%	9%	36%	9%	64%	82%
	Never		Sometimes		Always	
2. Do you find different ways to exercise when it's raining and you don't want to go outside?	64%	9%	27%	9%	9%	82%
3. Do you drink enough water after exercising?	27%	9%	45%	36%	27%	55%
4. I am in school for long hours and when I get the chance to chill, I just want to sit in front of the TV.	0%	18%	55%	64%	45%	18%
5. What I eat now is not going to make a difference for my health.	18%	9%	45%	18%	36%	73%
6. When I eat chips or cookies, I have to eat the whole bag.	18%	27%	36%	45%	45%	27%
7. I eat a lot when I am happy, sad, angry.	82%	82%	9%	9%	9%	9%
8. I easily feel upset.	27%	9%	64%	73%	9%	18%

DISCUSSION

The study targeted economically disadvantaged youth 6-18 years old located in Macon County, Alabama, a food desert with limited access to healthy foods, limited health education, and limited access to community physical activity. The 2014 preschool obesity rates in Macon County and Tuskegee, are 17.3% and 31.7% respectively. This study was designed to begin the discussion and introduce an alternative way to “break the cycle” of obesity in Macon County.

The study implemented interactive health education and physical activities with expectation of changing behaviors and attitudes towards healthy eating. Our measurements revealed that there was a positive increase in the attitudes of participants to recognizing that they can make choices, in that, unhealthy patterns of behavior, such as eating an entire bag of chips or watching television for a prolonged period of time, can be substituted by healthy behaviors such as riding a bicycle or walking more and eating more fruits and vegetables.

There were several limitations in our study. This study was limited by the fact that the study period was brief. In addition, at times, the answers provided by the children on the questionnaire were limited by their ability to fully comprehend the questions and also to carry over learned behaviors from the intervention sessions to make daily healthy food choices independently. There was also no easy way to measure other physical activities that they engaged in outside of the intervention sessions. Also, we could not use our results from the pedometers due to frequent malfunctions.

Table 4. Average scores Lifestyle Questionnaire Pretest and Posttest of Behaviors and Attitudes on Healthy Eating

Behaviors				Attitudes			
Participants	Pretest average scores	Posttest average scores	Score difference between pre/posttest	Participants	Pretest average scores	Posttest average score	Score difference between pre/posttest
1	2.00	1.88	0.12	1	2.25	1.88	0.37
2	1.75	2.25	0.50	2	1.75	2.25	0.50
3	1.63	2.25	0.62	3	2	2.25	0.25
4	1.88	1.88	0.00	4	2.25	2.13	0.12
5	2.63	2.38	0.25	5	1.88	1.88	0.00
6	2.63	2.63	0.00	6	2.13	2.25	0.12
7	2.25	2.00	0.25	7	2.13	2.25	0.12
8	2.25	2.25	0.00	8	1.88	2.13	0.25
9	2.13	2.13	0.00	9	1.88	2.13	0.25
10	1.50	2.13	0.63	10	1.88	2.13	0.25
11	1.88	2.00	0.12	11	2.13	1.88	0.25
Aggregate participants scores	2.05	2.16	0.23		2.01	2.11	0.23

Despite these limitations, our study provided a glimpse into the impact of our interventions on the behavior and attitudes of the children towards choices of foods, as well as, desire to participate in some physical activities. Although the results were not strong, we believe that health education and physical activity interventions positively influenced healthy eating attitudes through the several weeks of interactive interventions, that included visual aids, worksheets on balanced meals, gardening using fruits and vegetables, prepared and consumed vegetables, and fruit ‘smoothies,’ with kickball, relay racing, sack racing, bean bag toss, football, basketball, and a simulated jeopardy games. Some students demonstrated the ability to broaden their scope of exposure and understanding of healthy behaviors and attitudes (see table 4). We would like to see the results of a long term lifestyle program, at

least 2-3 times a week, combining health education and physical activity interactive interventions with continued research on behaviors and attitudes of healthy eating in children.

ACKNOWLEDGMENT

This research was supported by the Macon County Food Bank, Tuskegee Youth Safe Haven, the Tuskegee Chapter of Links Incorporated, Tuskegee University Occupational Therapy Department, Albert Schweitzer Fellowship, and Break the Cycle 12 of The Emory University Department of Pediatrics and SE PEHSU. This research was included in the “Break the cycle 12” conference held by the Southeast Pediatric Environmental Health Specialty Unit and Innovative Solutions for Disadvantage and Disability Sustainability Initiatives annually at Emory University; an interdisciplinary research and training program funded by the cooperative agreement from the Agency for Toxic Substance and Disease Registry (ATSDR). We are immensely grateful to Mr. Guy Trammel, site manager of the Tuskegee Youth Safe Haven who provided his pearls of wisdoms throughout the course of this research project.

Emory University, Atlanta, Georgia, USA

ABSTRACT

Approximately 3% of children in the United States have levels of lead in their blood above our currently established level of concern. Exposure to lead is a significant environmental health concern for children living in older housing, especially for low income and minority groups. Education and outreach programs can improve environmental health literacy regarding lead exposure and mitigation. Methods: We designed a curriculum to educate and change behaviors related to sources of lead and mitigation. The curriculum drew upon expert and community partner input. We carried out a one-time class pilot for 3rd, 4th, and 5th grade children at a metro Atlanta Boys and Girls Club. The class contained an interactive game, visual aids, and an outreach component through a parents' night. Curriculum performance was evaluated using student knowledge pre, mid-point, and post course surveys. Results: We observed increases following the program for five knowledge categories; Hazard identification, routes of exposure, characteristics of lead, exposure sources and mitigation. Mean scores in all categories were higher than 50% in a post-course evaluation. Discussion with parents following the program indicated a need and appreciation for information regarding lead exposures and health effects. Conclusions: This curriculum demonstrated evidence for an increase in environmental health literacy regarding lead exposure and mitigation. Students were able to identify sources of lead and understand best behaviors for reducing exposures after participating in the interactive program. Stakeholder and community engagement were beneficial in creating this curriculum. Large scale implementation and continued curriculum refinement is recommended.

INTRODUCTION

Lead is a metal that is colorless and odorless when dissolved in water, and is toxic. Children are at the greatest risk for both ingestion of lead contaminated materials and its corresponding long lasting adverse effects on cognitive function, cardiovascular and immune systems [1]. Children can be exposed in their homes from products coated or contaminated with lead such as paint, pottery, medicines, soil, dust, and water. Older homes pose a higher risk for lead exposure, as lead was only banned in paint in 1978 in the United States [1]. While elevated levels of lead in blood have been reduced significantly after the removal of lead from gasoline and paint, the Centers for Disease Control and Prevention (CDC) estimates that nationwide there are 500,000 children that have blood lead levels (BLLs) greater than or equal to 5 micrograms per deciliter ($\mu\text{g/dL}$). The BLL of $5\mu\text{g/dL}$ has been deemed the level at which children require case management to reduce exposure and mitigate effects [2]. In 2015, the CDC's National Surveillance Data program found 0.5% of children tested in the US had levels that are greater than or equal to $10\mu\text{g/dL}$ and approximately 3% of children were reported to have levels between $5\mu\text{g/dL}$ and $9\mu\text{g/dL}$ [2]. Since 2012, the CDC Advisory Committee on Childhood Lead Poisoning Prevention (ACCLPP) has stated that there is no safe BLL [1].

Race, socioeconomic status, and housing conditions are risk factors for elevated BLL's. The National Health and Nutrition Examination Surveys (NHANES) data and other studies have found that lead levels are higher among children who are non-Hispanic black, enrolled in Medicaid, have families with below median or income less than or equal to \$30,000, and/or live in homes built before 1946 [3-6]. Childhood exposure to a harmful built environment, specifically overcrowded housing, has been shown to perpetuate the cycle of social inequality later on in life [7]. Low income and minority communities are at the highest risk for such hazardous living conditions, creating a cycle where these groups who are at risk for a number of health and economic issues are exposed to potentially high levels of lead in older homes early on in life [8].

On a state level, the lead surveillance program by the Georgia Department of Public Health (GA DPH) reported that of the 120,369 children screened in 2016, 0.04% had levels greater than or equal to $10\mu\text{g/dL}$, and 2.02% had levels between $5\mu\text{g/dL}$ and $9\mu\text{g/dL}$ [9]. Children in Georgia are being exposed to lead in both their homes and schools. The 2000 Georgia state census reported that 23.6% of children under the age of six years live in homes that are below the poverty level, and 12.7% live in housing units built before 1950 [10].

Lead can also be found in drinking water often as a result of older service lines, pumping equipment, or fixtures. All buildings in the Atlanta public school district were tested for lead from water fountains and kitchen taps in 2016. Over 40% of the schools tested found levels of lead greater than 15 parts per billion (ppb) in at least one source. 3% of all sources tested had elevated lead concentrations [11]. 15 ppb is the level at which the Environmental Protection Agency (EPA) recommends actions be taken to reduce lead exposure [12]. Two neighboring school districts to Atlanta, Dekalb and Fulton, also tested their school systems in 2016/2017 and found that 3.7% and less than 3% of sources tested, respectively, had lead above 15 ppb [13, 14]. The effect of poverty on drinking water lead was observed during the Flint water crisis. From April 2014 to October 2015, approximately 99,000 residents of Flint, Michigan were exposed to drinking water with high levels of lead after switching from the Detroit

Water Authority to the Flint Water System. The Flint Water System did not properly control for corrosion, and lead reached the water system through pipe corrosion. A significantly higher percentage of children had BLL's greater than 5 µg/dL after switching water systems [15]. The largest increases in lead concentration were seen in socioeconomically disadvantaged neighborhoods [16].

Figure 1. Depiction of where our program intends to break the cycle of environmental health disparities. Overall, education to increase environmental health literacy and awareness will reduce exposure to lead in the home environment.

Due to the prevalence of lead poisoning nationwide and in Georgia, we aimed to reduce lead exposure and disrupt the cycle of environmental health disparities among children. Environmental health disparities arise from a complex sequence of factors relating to compound risk personal characteristics, environmental risk, environmental characteristics, health risk, and health characteristics. Figure 1 is a modified environmental health disparities cycle from a previously developed general model [17] with our project's aims to alleviate environmental characteristics and health risks relating to lead exposure. We intended to disrupt the cycle by increasing environmental health literacy among children and their families.

Health literacy is defined as “the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions” [18]. Environmental health literacy is then the “understanding of the connection between environmental exposures and human health” [19]. Because household lead exposure is preventable, the intent of our program was not only to increase environmental health literacy in children and families about household lead hazards, but also to provide them with accessible tools to screen their homes and connect them with local professionals. We intended for our project to raise awareness about household lead mitigation factors to help reduce toxicant exposure which has the potential to reduce cases of neurotoxicity, learning disabilities and behavioral disorders attributed to lead poisoning.

While the EPA, CDC, and other agencies and organizations have developed educational materials online and in-print for children and adults, they have not monitored and evaluated the success of their programs. To address this gap, our program included outreach to parents, as well as monitoring and evaluation components. We used the EPA's Recipes for Healthy Kids and a Healthy Environment as a template for our curriculum to "excite kids about environmental health and empower them to take steps in their everyday lives" relating to household lead hazards [20].

OUR STUDY

To develop our pilot curriculum, we collaborated with local partners and stakeholders, as community-academic partnerships and broad expertise are beneficial to environmental health literacy research [19]. Our initial and primary curriculum development stakeholder was the EPA Region 4's Children's Health and Lead Programs. The EPA provided educational materials from their previous programs and mentorship regarding curriculum development. We also researched other publically available materials on lead education to inform our program development. We included experts from the Georgia Department of Public Health and the CDC to assess the accuracy of the information in our program. Because the Recipes for Healthy Kids and a Healthy Environment was originally designed through a partnership with the EPA and Boys and Girls Clubs (BGC), we sought out a local BGC. We contacted several local BGC's that were located in areas where older housing and lead exposure could be a potential issue. We partnered with the Samuel L. Jones BGC in Decatur, GA due to its close proximity to the research team. We wanted to create a project that could be helpful within our own community and build a close partnership between the research team and the BGC. In addition, we believe that this project could be the impetus for more collaborations between Emory University Students and the local community. The 2010-2014 census reported the median household income of Decatur as \$73,679. By race, Decatur is 69.8% white, 22.2% black, 4.4% Asian and 3.6% other [21]. In the Oakhurst neighborhood directly surrounding the Samuel L. Jones BGC, over half of the homes were constructed before 1950, creating an area at high risk for exposure from lead paint [22].

Curriculum Design

We designed our class to improve behaviors related to lead exposures (see Figure 2) for the students in the class. In addition, we intended to engage not only the individual students but their families and peers. We aimed to do this by advocating for students to teach their younger siblings, friends, and parents about the hazards of lead to increase household environmental literacy.

Figure 2. The five core behaviors we intended to change with our curriculum based on our Theory of Change. Each behavior is paired with a vignette photo used in the course itself.

Figure 3. The curriculum was divided into the above five sections. All sections were designed to increase the environmental health literacy of the students regarding lead exposure.

We designed the curriculum using chapters from *Recipes for Healthy Kids* and a *Healthy Environment* as a framework which was developed for children aged 9–13 years [20]. Project stakeholders suggested tailoring our program to this age group, as they would be able to grasp the concepts and likely have siblings under the age of 6 who are at the highest risk for adverse effects resulting from lead poisoning. The introduction of our curriculum contains the course objectives and key vocabulary terms (see Figure 3). We then created a five-part lesson plan based on these key learning elements. To supplement the verbal information of our class, we generated a variety of course materials including visual aids (Appendix A), an interactive game (Appendix B), and take home pamphlets for parents (Appendix C). The take home pamphlet was designed to be a stand-alone item, able to inform adults who were not present for the program, and a visually appealing reference and contact guide. We wrote a script for the entire lesson to create a structure that can be followed by others who want to implement the program (Appendix A). We pre-tested the program with children of the target age group and surveyed them on what parts were engaging and what information they retained. We also included additional resources as take home exercises to supplement the content delivered in the class (Appendix A). These additional resources were not piloted in this study.

Curriculum Outline

The curriculum was divided into five sections as shown in Figure 3. All sections were designed to increase the environmental health literacy of the students regarding lead exposure:

- Section One: We opened the program with an icebreaker game designed to have the students interacting verbally and moving around the room. The icebreaker game consisted of “get to know you” questions and some questions pertaining to lead sources and exposures.
- Section Two: After the icebreaker game, we defined our three key terms; Hazard, Exposure, and Lead. In Section Two, we focused on describing lead as a metal and why it was dangerous.
- Section Three: We synthesized the first two sections as we presented lead exposures and hazards. The verbal descriptions were coupled with staged pictures of exposures that the students were asked to interact with and explain. This dual medium provided the opportunity to engage multiple learning styles.
- Section Four: We asked children to participate in an interactive “detective game”, where the students were asked to explore the room and identify pictures of lead sources and mitigating behaviors. The game was designed to stimulate critical thinking through physical activity.
- Section Five: Everyone was brought back to a classroom configuration for Section Five. Here we reiterated the key terms and concepts from the program. This reinforced the main verbal descriptions from the curriculum.

Lead Screening

We had an additional research goal of promoting screening for lead in the homes of the children who participated in the pilot program. We distributed 3MTM LeadCheck™ swabs, which are a safe and reliable first assessment of lead levels on home surfaces to parents [23]. We designed a text-based survey using Telerivet [24] for parents to relay the results of their test to the research team. The text application also provided parents with information on professional resources if the lead screening swab indicated a positive result. To assist parents in performing the tests, we also created step-by-step instructions in color with visual aids (Appendix D).

Pilot Study Design

We carried out the pilot program in March of 2017 at the Samuel L Jones BGC in Decatur, Georgia. The students who attended the class were a convenience sample but represented the target age range that was available at the club that day. Forty-one children in 3rd, 4th, and 5th grades attended the program. Four instructors and two BGC employees were present for the class. Each developer taught part of the curriculum. Two identical visual aid

stations were set up on either side of the room due to the large class size. Two instructors simultaneously taught the lesson at each station to reduce the overall class size. The lesson was divided into five sections (see Figure 3) and took place over 1 hour and 15 minutes.

After the program, we gave parents/guardians a packet that included an informational pamphlet, a lead screening test and instructions, and contact information for expert local resources related to residential lead exposure. Also included in the packet was a flyer advertising the curriculum's parents' night. One week following the lesson, we hosted parents' night at the BGC to reinforce the behavior change outputs, such as recognizing potential sources of lead in the home. The event intended to bring together experts from the EPA, CDC, and GA DPH to discuss exposure sources, mitigation strategies, and publically available resources with parents. On the day of parents' night, we had a small group of parents, the developers of the program, and a representative from the CDC to answer questions by parents. After the parents' night, we proactively met parents picking up their children from the BGC, introduced ourselves and our project, and answered their questions. We also distributed program materials to all club parents as they picked up their children, in order to expand the impacted audience.

Data Collection and Analysis for Program Evaluation

Student knowledge comprehension was tested at three time-points throughout the program: before the class, in-class during the interactive detective game, and one week following the class (Appendix E). Before the presentation of our curriculum, we distributed a paper survey on understanding of hazards, exposures, and lead. The detective game sheet assessed knowledge directly following the presentation of all information contained in the curriculum. The children's answer sheets for the detective game served as a midpoint evaluation assessing knowledge retained immediately following the lessons. While each student completed their own answer sheet, they worked in small groups to find the pictures throughout the room. This is different from the pre-class survey which was done individually. For the post-intervention evaluation, we revised the pre-class survey for clarity and formatting. We administered it using an online Google survey to determine knowledge retention one week after the program. The selection of post-course survey participants was random and uninfluenced by any factors known to the research team.

The pre-course survey was the counterfactual in this program evaluation. Student answers from all time points were analyzed for differences in mean class knowledge using pre, midpoint, and post scores.

Program Ethics

No identifying personal information was asked for in the surveys used for course evaluation or the home screening kits, ensuring confidentiality. Verbal proxy consent was given by the BGC for all children who participated in the class with the stipulation that no identifiable photos would be taken and distributed of the children.

FINDINGS

We divided the pre, in-class, and post knowledge surveys into five assessment categories: Hazard Identification, Routes of Exposure, Characteristics of Lead, Exposure Sources, and Mitigation (see Table 1). We calculated the mean score of each category at each time point to determine change in knowledge. Figure 4 shows the change in category understanding before the program began, during the detective game previously discussed, and one week after the curriculum was implemented. The pre-course survey was administered on paper to 41 children that were present on the day of the class while the post-course survey was administered digitally one week later to a convenience sample of 16 children that participated in our class.

Table 1. Five main curriculum concepts

Assessment Category	Learning Goals	Example Question
Hazard Identification	-Define “hazard” -Identify typical household hazards	“Name a dangerous thing from the picture above (Appendix B) and explain why this is dangerous.”
Routes of Exposure	-Define “exposure” -Explain major routes of exposure	“How can you get exposed (or come into contact) with harmful products or chemicals?”
Characteristics of Lead	-Describe lead as a harmful metal -Outline the potential negative health impacts of lead	“Why is lead harmful to you, younger siblings, or your friends?”
Exposure Sources	-Understand potential sources of lead in the home -Be able to explain these to younger siblings or friends	“Name five hazards related to lead in the room.”
Mitigation	-Practice behaviors that reduce lead exposure in the home	“Draw and label three foods that reduce the bad effects of lead.”

Note: The five main concepts of the curriculum including goals and example questions that were used in the actual curriculum.

Figure 4. Change in category understanding before the program began, in-class through the detective game, and one week after the curriculum was implemented.

Questions relating to Hazard Identification assessed the children's ability to identify exposures that could harm their health in the household scene poster (Appendix B) (pre: 72.3%; post: 95.8%). Common answers were: the snake in the garden, the hot grill, and the power tools. The other concepts tested were: identification of Routes of Exposure (ingestion, inhalation, dermal contact) in which a hazard can affect the body (pre: 22.7%; post: 81.2%), Characteristics of Lead (pre: 4.8%; mid: 48.4%; post: 75.0%), Exposure Sources where people could encounter lead (pre: 12.7%; mid: 72.%; post: 68.7%), and healthy behaviors to Mitigate the effect of lead on the body or reduce lead exposure (pre: 11.8%; mid: 67.5%; post: 57.3%). Scores that do not have a midpoint monitoring score were not evaluated during the interactive detective game. Mean scores increased after the class. There is attrition between in-class class monitoring and the assessment one week later for the Exposure Sources and Mitigation categories. We did not receive results from the voluntary take home screening tests and text message surveys.

DISCUSSION

The baseline (pre-class survey) and follow-up (post-class survey) knowledge assessments were critical components of our project evaluation as it provided a tool to measure the effectiveness of our materials and methods. We expected Hazard Identification scores to be the highest pre-class score because it asked the children to identify common household and environmental items in the visual (Appendix A), that could be harmful to their health. We attribute the increase in score after the class to many students not answering the question in the pre-course survey because of distractions in the room and confusion about instructions.

Scores for routes of exposure, characteristics of lead, exposure sources, and mitigation all increased from the pre to the post class evaluation. This increase is a possible indication of the effectiveness of our curriculum across all four areas. The detective game worksheet was a useful midpoint monitoring point for the program across three areas: characteristics of lead, exposure sciences, and mitigation. The Characteristics of Lead category scores increased at the midpoint, and from the midpoint to the final evaluation. We hypothesize this increase is due to a second iteration of the concept during the wrap-up after the detective game monitoring point that added clarity. The Exposure Sources and Mitigation category scores were higher during the midpoint monitoring than the final monitoring, but this drop after a one-week interim is expected. We surmise that attrition in knowledge over time is expected across all the categories. There was a reduction in sample size between children who submitted a pre-class survey and a post-class survey which was primarily due to logistical issues at the BGC

Class Logistics

Due to limited availability of space, the pre-planned room set up was not implemented on the day of the class. The initial plan was to have a total of four rooms with 10-15 children in each, with the class administered by one of the four developers of the project. A staff member of the Boys and Girls Club also planned to be part of the class to assist with logistics while

the class was in session. The actual class was conducted in one large room that housed all 41 students, four instructors, and two BGC staff members. Despite the large class, the children remained engaged in the class, answered questions posed to them, and asked questions on the content of the class. Transition times of the different sections were not seamless due to the class size, and this contributed to the class exceeding the originally allotted time of one hour. The pre-course survey also took more than the allotted time due to some difficulty in understanding some of the instructions.

Parental Engagement

Parental engagement was used to inform legal guardians of all children at the BGC. Despite the low small group attendance, the parents' night was engaging with important questions raised and addressed. Parents asked questions that were focused on lead contamination in the water system in Flint, Michigan and how lessons learned can be adopted to prevent recurrences in other locations across the country [16, 17]. They also raised questions on the recent issue of lead detection in school water sources, and what danger that poses to their children.

Recommendations

As this was a pilot exercise, we believe there to be three primary recommendations to improve large-scale implementation – smaller class sizes, reinforcement of materials, and incentivizing parent's night.

Due to timing and logistical issues, we recommend small class sizes of 10-15 children to enable smooth transitions between sections of the curriculum. In addition, smaller class sizes would allow the team to adapt the lesson plan to specific needs, provide more individualized attention, allow for children to ask more questions during the lesson, and minimize distractions.

Additionally, we suggest reinforcing the curriculum at later time points and keeping the classroom posters accessible after each implementation as a reminder of the course content.

The parents' night was an important component of our program because it enabled us to inform adults on the hazards of household lead exposure. However, parent participation rate for our program was low. Feedback from the BGC highlighted that lack of incentivizing parents night was a contributing factor. We also received feedback suggesting that children should have been reminded about parents' night at the end of the class. We hypothesized that parents may have been oversaturated with information contained in the packages we put together. This large amount of information may have led to low participation at the parents' night because they may have not seen the flyer advertising the event. It is important to emphasize that the incentive adopted by future users of this curriculum should be tailored to the setting where it is implemented to ensure effectiveness.

CONCLUSION

Lead exposure is deleterious to health, and children age five and under are more susceptible to adverse health outcomes from exposure [1]. For this reason, we chose to design and implement a pilot educational program for children centering on lead exposure and mitigation at a local Boys and Girls club. We focused our intervention on increasing environmental health literacy regarding the issues of lead exposure and mitigation. Developing the curriculum required collaborating with a multi-disciplinary team that contributed their respective expertise to its success. We found significant improvements among the class participants in five knowledge categories: hazard identification, routes of exposure, characteristics of lead, exposure sources and mitigation. These results demonstrate increased environmental health literacy on the subject of lead exposure among children who participated in the class. Environmental health literacy research and education such as this curriculum should be replicated and brought to individuals and communities at risk for environmental exposures to create a large impact [20]. The curriculum was presented to EPA's Office of Children's Health Protection at the invitation of their Director for their feedback and comments. Currently, EPA intends to incorporate this curriculum in its Recipes for Healthy Children and a Healthy Environment Curriculum which is implemented nationally and especially targeted for low income communities and families.

Unfortunately health disparities exist and perpetuate the cycle of toxic environmental exposure to low income families. By incorporating a low-cost interactive educational curriculum, we intended to disrupt the cycle of lead exposure and its effects by informing children and families of the hazards of lead toxicity, preventative measures and tools and resources to screen and remove lead in their homes. We have made our curriculum available to the EPA, other governmental institutions and private organizations who can use our curriculum as a template and tailor it to their specific audiences with respect to demographics, culture, and language.

ACKNOWLEDGMENT

We thank the Break the Cycle Program for financial support. We also thank the EPA and CDC for helping with curriculum development. Finally, we would like to thank the Boys and Girls Club for generously partnering on the pilot program and the children who participated.

APPENDICES

Appendix A: Curriculum Outline and Script (Includes Visual Aids and Additional Materials)

Break the Cycle Year 12
Lead Education for Elementary Age Children
Curriculum Outline

Snapshot

Preparation and Materials:

- Nametags
- Visual Aids
- Worksheet for interactive game
- Pencils
- Red and Green Post its or sticky notes
- Posters used in Part 2
- Detective worksheets
- Colored photos of additional hazards/mitigation factors not in the room
- Props of hazards/mitigation factors (fruits, brooms etc.)
 - Hide some of these props in areas that are not obvious to find
 - Include props that are not part of a lead mitigation plan but may be found in homes

Objectives: Students will be able to

- Define hazard and exposure
- List potential sources of lead in their environment
- Understand how lead exposure can impact their health
- Understand how their actions can help reduce their lead exposure

Vocabulary

Lead, Exposure, Hazard

Procedure

1. Introduction and Vocabulary (10 minutes)
2. Where does lead come from (10 minutes)
3. Lead Exposure and Hazards (5 minutes)
4. How to limit lead exposure (15 minutes) - This lesson aims at educating students on identifying and practicing steps geared at reducing their exposure to lead in their environment, as well as identify foods that reduce the absorption of lead from diet and reduce storage in the body. This will be done with an interactive game whereby children will play the part of a detective and explore a room to determine hazards and mitigating factors.
5. Take-Home Talk (5 minutes)

Lesson: Lead in the environment

1. Introduction and Vocabulary (10 Minutes):

EXPLAIN: We are students and scientists from Emory University. We study how the world around us can affect our health in good and bad ways.

ASK: We are going to play a quick game to get to know each other. Everyone get up and stand in a circle. We are going to ask a few fun questions. If your answer is yes, run to the other side of the circle. If your answer is no, stay on the edge of the circle.

- Who has a birthday in the summer?
- Who has a birthday in the winter?
- Who has a name that has a “C” in it?
- Who likes to eat macaroni and cheese?
- Who has younger siblings?
- Who has ever played in the dirt or a garden?
 - Who has brought the dirt inside?
- How many of you have helped your parents paint?
 - Did you ever notice paint peeling or chipping?
- Who has helped their parents cook in the kitchen?
 - Who has been warned about touching a hot stove?

EXPLAIN: The hot stove was dangerous for me to touch. Another word for something dangerous is hazard.

Everyone come back and sit down around the poster so we can talk more about some other hazards.

A hazard is something you can come in contact with that could be dangerous. Hazards can be found in many different places, but can usually be avoided if you are careful.

ASK: Can you name other hazards around your home or school?

EXPLAIN: You can be exposed to things when you come into contact with something in your environment. This can be by breathing, smelling, touching, eating, or drinking something.

ASK: For example, how can you be exposed to a hot stove?

EXPLAIN: You can be exposed to a hot stove if you touch it.

ASK: Now, if a stove is turned off and cold, is it dangerous and a hazard when you touch it?

EXPLAIN: It’s only dangerous when it’s turned on and hot and you touch it.

There are two parts to a hazardous exposure, they have to be a hazard (like a stove being hot) AND you have to be exposed to them (like touching the stove).

ASK: Can you tell me again how you can be exposed?

Answer: touch, eat or drink, breathe in, hear, smell

DO: Show Poster #1

EXPLAIN: Here is a picture that might have some different hazards you have seen before. Like the sun. The sun on its own is not a hazard but if you get too much exposure like by staring right at it or laying out all day then it is not good for you.

On a sunny day, you should wear sunglasses to protect your eyes and sunscreen to protect your skin.

ASK: Can anyone see other hazards on this picture? Grab a red sticky note and come up to mark it on the poster. Can you tell everyone in the room why you think this is a hazard? How can you become exposed to that hazard? *(Let/help kids identify 5 hazards)*

Example Hazards [Exposures]: Traffic (speeding cars, air pollution), Grill (touching hot grill, starting a fire), Pool (drowning), Sun (sun burn, in your eyes), Ladder (falling off ladder), Paint (getting it on your skin), Power Tools (touching the sharp parts of them), Soccer Ball (mom can trip on it), Dirt (Baby playing in the dirt and eating it),

2. Where does lead come from? (5 minutes)

ASK: Can anyone name a type of metal? **Have Vignettes up and behind the speaker.**

EXPLAIN: Some types of metals are silver, gold, and iron that are safe for us to wear or use in buildings. Lead is another metal. Lead is a poisonous metal that harms our bodies if we are exposed to it.

ASK: Who has heard of lead?

EXPLAIN: Lead has been in the news recently because there are some cities in the US that have lead in their drinking water. Old pipes that carry water to your sink can have lead in them. Sometimes that lead can leave the old pipes and get into the water you drink.

People used to put lead in paint and even gas for cars. Then scientists found that lead was dangerous to people's health and so they stopped using it in paint and gas. But because lead used to be in paint, some older homes and apartments may still have that lead paint on the walls. Or if it's not on the walls, there can be little pieces of the paint that chip and peel off which can fall on the ground.

Lead is also sometimes found in some toys or jewelry that some people play with or in the soil and dust.

EXPLAIN: If you are exposed to lead, then you could get lead poisoning. Even if you only come into contact with a small amount of lead it can be harmful to your health partially because our bodies don't get rid of lead well, it stays in our bodies for a long time. Lead poisoning can make it harder to pay attention in school, or remember what you learned in class the day before. It is especially not good for babies and young kids. This means that pregnant mothers also have to be careful about lead exposure to protect the baby growing inside of them.

ASK: How tall were you guys when you were 2? And see much you've grown since then! Now, why do you think lead is not good for babies like 6 month olds and young kids like toddlers?

EXPLAIN: Babies and young kids are still growing. As they get bigger and taller, their insides like their brains and immune system, which helps them fight off disease, grow and become stronger. If the babies or young kids have lead poisoning, it can hurt the way that their insides grow and can make it harder to learn or hear or speak and sometimes can change how they behave. Lead is also harmful to adults because their bodies don't need it but it is especially a problem for children.

ASK: How many of you sucked your thumb when you were little? Why might this be bad for babies?

EXPLAIN: Because they may have touched something with lead on it, like paint or certain toys, and then when they put their thumb in their mouth they are exposing themselves to lead.

Since lead is hazardous, scientists have ways to find lead in our environment. Now we're going to talk about where lead can be in our environment and ways to stay safe from becoming exposed to lead.

3. Lead Exposure and Hazards (10 Minutes)

DO: Poster #2 (Specific lead hazards and exposures - **Vignette Images**). Let's take a look at these pictures. Just like before, there are some pictures of hazards in the top 4 pictures, but this time each image has a lead hazard in it.

Come up, grab a red sticky note, and put it on the hazard. How do you think you could be exposed to that hazard?

(Refer to boy in dirt) What is the child in this photo doing? That's right, she's playing in the dirt. How could she be exposed to the dirt while she is playing? On her hands. What do little kids sometimes do with their hands while they are playing? Right, they sometimes put their hands in their mouths even if they are dirty.

(Refer to the boy drinking water) What is the boy in this picture doing? Right, he's getting water from the faucet and then drinking water. And what could be in his water if he lives in an old house? Yes, there could be lead in the old pipes in houses.

(Refer to the baby with toys) What is the baby in this picture playing with? Toys or jewelry could have lead in them or get dust on them. And how could the baby be exposed to the lead in the toy? If they put the toy or their hands in their mouths, they can expose themselves to the hazard.

(Refer to girl near window) What is the child doing in this photo? Great! She is touching the window. How can she be exposed to lead? She is very close to the window sill and dust can gather here, it may have lead in it and it can get on her hands. Again, where do children put their hands? Sometimes in their mouths.

ASK: Now that we've seen some hazards that have lead in them, can anyone think of some ways to stay safe from getting exposed to them?

EXPLAIN/DO: Let's look at the pictures of hazards from before and figure out some ways to stay safe from lead. When you think of a way to stay safe from lead, come up and put a big green sticky note over the red one and tell us why.

(Refer to boy in dirt) Remember we talked about how playing in the dirt can expose you and little kids to lead. How could you protect yourself and others from the lead if you get dirt on your hands or clothes? Right, you can wash your hands and clothes. And remember to watch any younger siblings or friends so they don't put their hands in their mouths.

(Refer to the boy drinking water) How can you stay safe if there is lead in the drinking water? There are filters your family can buy to remove lead from the drinking water or you can use bottled water.

(Refer to the baby with toys) How can you stop babies or little kids from getting exposed to lead in toys? Be sure to always be on the lookout for people younger than you when they are playing with toys. You can then tell them not to chew or lick the toys and to always wash their hands after they play.

(Refer to girl near window) What could you do to clean the windowsill and keep the lead away from this girl? You can use a wet rag or mop with a cleaning solution to clean lead and dust from surfaces around a room. It's also important to keep younger kids from eating the paint or dust on the windowsill. Sometimes it can taste sweet, but it's very dangerous.

(Man mopping in the kitchen) What is the man doing in the picture? Why is he mopping the floor? Great! He is trying to get the dust off the floor. Who remembers what can be in dust? The dust on the floor may contain chipped paint from the walls, and can cause exposure to lead.

(Woman on the phone with the hotline) What is the woman in this picture doing? She's on the phone. Who is she calling? The lead hotline. Why would she be calling the lead hotline? The lead hotline can help you and your family if there is lead in your house. Does the paint behind her look old and chipped? Could be a hazard if she is exposed. Who can help

you when you call the hotline? Lots of people like doctors and people who can clean up dangerous paint from your home.

There are some lead screening kits that your parents can use to see if there is lead in your home. These kits can be used on metal surfaces, paint, dust, your computer, couches, fabric, clothing, or rugs, really anywhere you think might have lead. We'll be giving your parents a lead screening kit when they pick you up today so remember to tell them to test your home. After they use the kit in your home, you can help your parents text us to let us know if you found lead in your house or not.

EXPLAIN: We've learned a bunch of ways to stay safe from lead in the environment. Now, let's talk about one really good way to prevent health problems if you are exposed to lead. Eating certain foods that have iron like fish and chicken, or foods high in calcium like milk and cheese foods with a lot of Vitamin C like fresh fruits and vegetables, can stop lead from getting into your body and piling up. This keeps you healthy and safe from lead poisoning.

ASK: What are some healthy foods that you guys like to eat?

4. How to limit lead exposure? (15 minutes)

Introduction of game

EXPLAIN: Remember, a hazard is something you can come in contact with that could be dangerous. Hazards can be found in many different places, but can usually be avoided if you are careful. An exposure is when you come into contact with a hazard. All on its own, a hazard can't hurt you, but when you are exposed, that's when it can be dangerous.

ASK: Today you are all lead detectives. I would like you to get up and search the room for clues and signs for possible lead hazards and exposures in this room. There's a prize for every detective! *Give each child a detective sheet.*

Visuals:

Necklace, apple, chicken, yogurt, cake, faucet, hand washing, orange, dirt, pear, candy, cheese, lead hotline, dusty chair, paintbrush, potato chips, mop, milk, french fries, gloves, banana, fish, duster, dusty desk

EXPLAIN: I would like you to go around this room and find 5 hazards in this room. Then, find 4 ways to clean up this room to reduce being exposed or coming into contact with lead. Next, find 3 foods that will help reduce the bad effects of lead. Last, find 1 place to do a lead screening test. Use your worksheet to write down what you find. **There will be some pictures in the room that do not belong on the detective sheet.**

DO: Allow kids to walk around the room to identify hazards in the room and ways that they can prevent or reduce the hazards. The instructors will walk around the room to help and ask critical thinking questions to the students.

ASK: *When the kids come back together after 15 minutes.* What did you all learn from being lead detective? What sorts of things did you find around the room?

DO: Go over the correct possible answers for each section of the detective sheet and let the kids correct their sheets if they have incorrect answers. Tell them to look out for the incorrect answers.

Answer Key for Detective Sheet

Lead Hazards: Dirt, dusty chair, paint brush, faucet

Protective: mop, gloves, lead hotline, hand washing

Good foods: apple, chicken, yogurt, orange, pear, cheese, milk, banana, fish

Where to do a test: metal surfaces, paint, dust, computer, couches, fabric, clothing, rugs

Bad foods: cake, french fries, potato chips, candy

5. Take Home Message

- What was the coolest thing you learned from talking about this topic with family and friends?
- Lead is a metal that is harmful to your health. It can hurt your brain and immune system.
- Places where you can find lead include paint from buildings, contaminated soil and dust. Other sources may include pipes with lead and toys painted with lead
- Washing your hands, washing fruits and vegetables that you eat, and eating certain foods can reduce chances of being exposed to lead or prevent lead from staying in your body
- I also want you to talk to your parents and other adults about what you learned today.
- I have some activities for you to take home and show your parents. I will be at Parent's Night next Friday so tell your parents to come and learn more about lead from us.
- Thanks!

Take-Home Talk with Parents:

- Lead is colorless, odorless and tasteless, so we may be exposed to it without even knowing it
- In Flint, MI the water source was changed to a polluted river that was very acidic. Because the water treatment plant did not treat the water properly, this acidic water went through the pipes into people's homes. This acidic water damaged the lining of the water pipes. The water pipes were very old and therefore had lead in them. Since the lining has been damaged, the lead was still able to contaminate the water supply even though the source has been changed. The lead contamination will not stop until all the damaged pipes are replaced. People can drink and use the local water if they

have a special filter that removes the lead (this is not the same as the water filters we regularly find at the store, they must be specially designed to remove lead).

- Atlanta Metro Schools recently tested the drinking water fountains in their schools for lead. They found lead in several of the fountains and closed those fountains. If your child attends a school that tested and found lead you should have received information from the school about it. You can contact your child's school office if you are unsure if they tested for lead or found lead.
- 4 million households in the US have children living in them that are exposed to high levels of lead.
- Lead exposure can be prevented by washing hands whenever they get in contact with dirt from working in the garden or playing, cleaning dusty surfaces with a mop, or sponge and general all-purpose cleaners, avoid playing in rooms that are dusty, avoid eating chipped paint, and using special, lead specific, filters on water that may be contaminated with lead, or using bottled water.

Additional Resources: Lead Awareness Resources for Teachers (Grades 3-5) - Lesson plans, posters, and online activities for students

Class Activity:

- EPA: Get the Lead Out Relay - A class activity to emphasize that certain foods can block the absorption of spread of lead in the body. This class may be for younger children below grade 2.
 - Instructions - construct a tri-fold poster of photos and labels of food by their content (use chart below)
 - Place the photos and labels of food randomly on the tri-folder poster and include foods not listed such as seafood, nuts and grains
 - Divide the class into groups and ask the students to run up and identify lead blocking foods on the poster

Iron	Calcium	Vitamin C	Fat Foods
Lean Meat (turkey, chicken)	Milk	Oranges	Bacon
Liver	Cheese	Grapefruits	Cakes
Steak	Yogurt	Potatoes	French Fried
Dried Peas	Greens	Bell pepper	Cookies
Beans	Cottage cheese	Watermelon	Sausage
Dark Greens		Tomato	Ice Cream
			Chips

Games & Activities:

- Word Search Game - A fun game to print and complete where you have to find the words hidden in the puzzle.

- Coloring Activity 1 - Coloring book with a story for children to follow to understand exposures and hazards to lead (Charlie Goes to Town)
- Coloring Activity 2 - Placemat for children to color and use at home to remind parents about behaviors to do to reduce lead contamination in the home

Appendix B: Detective Game

Name: _____			
Grade: _____			
Instructions: You are on a mission to keep your family safe! To complete this mission, you must: - Find 5 hazards related to lead in this room. - Find 4 ways to clean up this room to reduce coming into contact with lead. - Find 3 foods that will help reduce the bad effects of lead. - Find 1 place to do a lead screening test. - Answer why is lead bad for you in one sentence? You may also draw your answers on the back of this sheet.			
Hazards Related to Lead in the Room: 1. _____ 2. _____ 3. _____ 4. _____ 5. _____		Ways to Reduce Contact with Lead: 1. _____ 2. _____ 3. _____ 4. _____	
Draw and Label Foods to Reduce Bad Effects of Lead:			Where to do a Lead Screening Test:
Food 1	Food 2	Food 3	1. _____
Why is lead bad for you? _____			

Appendix C: Take Home Pamphlet

Hazard: Why is Lead Harmful? Lead is a poisonous metal that is bad for our bodies. It is colorless, odorless, and tasteless. Lead poisoning can cause learning, hearing, and behavioral problems. • Pregnant women who are exposed to lead are at risk for miscarriages or low birth weight. • Young children are at higher risk because their brains and immune systems are developing. • Lead can harm a child's brain, kidneys, and other organs. • In 2014, more than 2,500 children in Georgia had elevated blood lead levels, according to the Georgia Department of Public Health.  Exposure: Where is the Lead? Paint • Homes built before 1978 are more likely to contain lead-based paint. • Lead-based paint is a hazard if it is peeling, flaking, chipping, rubbing off, or cracking. • The break-down of paint can make lead dust in the home or mix lead into the soil if the paint is on the outside of the building.	Other Sources of Lead • Include drinking water from lead pipes, lead-based paints, toys, dusty household furniture, artificial turf, and pottery.  • Gardens around buildings that have lead-based paint can be contaminated.  Children can become exposed when they— • Eat paint chips or soil that contains lead or put their hands in their mouths after touching these objects. • Eat food from gardens that are polluted with lead. • Breathe in lead dust, especially during home repairs that break down painted surfaces.	Foods that Protect Children from Lead Iron-Rich Foods • Lean red meats, fish, chicken, and iron-fortified cereals.  Calcium-Rich Foods • Milk, yogurt, cheese, and green leafy vegetables (spinach, kale, collard greens).  Vitamin C-Rich Foods • Fresh fruits and juice from oranges, grapefruits, and tomatoes. 
---	--	---

If you Think your Home has High Levels of Lead:

- **Don't try to remove any paint yourself!**
- Get your home tested for lead if it was built before 1978.
- Get your kids tested for lead by their doctor, even if they seem healthy.
- Do not use imported pottery to store or serve food or water.
- Always wash your hands with soap before eating.
- Get your tap water tested for lead.
- Wash children's hands, bottles, pacifiers, and toys with soap and water.
- Regularly clean floors, window sills, and other surfaces using wet cloths or wipes to remove dust.

- Wipe shoes before entering the house.
- Use a certified contractor for any home repair.

If you rent...

It is your landlord's responsibility to keep paint in good condition. Report peeling or chipping paint to your landlord, and call your health department if the problem continues.

Contact Information

Below is a list of contacts that may be useful if you find lead, or if you think there is lead in your home, water or environment:

- **Family Pediatrician**
Call and schedule an appointment with your child's pediatrician as soon as possible.
- **GA Department of Public Health**
Phone number: 1-800-438-7442
Direct number to Lead Poisoning Prevention Program: (404) 657-6534
Hours: M-F: 8:00am - 5:00pm EST
- **Environmental Protection Agency (EPA) Lead Hotline:**
Phone Number: 1-800-424-LEAD [5323]
Hours: M-F: 8:00am - 6:00 pm EST
- **EPA Safe Drinking Water Hotline**
Phone number: 1-800-426-4791
Hours: M-F: 8:00am - 6:00 pm EST

Clean and Safe Homes

Keeping Kids Safe from Lead

Appendix D: Lead Screening Test Instructions

TAKE HOME LEAD TEST INSTRUCTIONS

How to use the DTMTM LeadCheckTM Swabs

Keep away from children. Contact medical professional. Swabs are intended to use only in contact with you. These Swabs and Confirmation CardTM into the package after use.

STEP 1: Squeeze and crush the point, marked A on the tube. Keep the glass tube inside the cardboard tube.

STEP 2: Squeeze and crush the point marked B on the tube.

STEP 3: With the white swab tip facing down, shake vigorously to mix.

STEP 4: Gently squeeze the tube, at joint A and B until yellow liquid comes to the tip of the swab. The lead is now ready for testing.

STEP 5: Squeeze the tube gently while rubbing the swab tip on the surface you are testing for 30 seconds. If the tip turns red, refer to the lead awareness pamphlet for contacts.

STEP 6: To make sure your result is working correctly, use the Confirmation Card. Rub the activated swab tip on one dot of the card. If the dot does not turn red, that swab is defective. Use a new swab.

Refer to package directions for confirmation and details on specific surfaces.
Text "LEAD" is 218-363-5886 after you finish the first step to send in your results and get more information about lead.

Appendix E: Monitoring Items (Pre/Post Knowledge Surveys)

Facts about Covid - Knowledge Survey

Circle _____

Here are five questions about the environment and health. Answer as many as you can. It is okay if you skip some the answer.

- A. Which door is the most dangerous thing burning picture above _____
- B. Why is this item dangerous? _____
- C. Which door is the most dangerous thing burning picture above _____
- D. Why is this item dangerous? _____

- E. Which door is the most dangerous thing burning picture above _____
- F. Why is this item dangerous? _____
- Questions 1:
- How can you get rid of or remove the most dangerous thing burning picture above? Choose all answers that are correct.
- 1. Using a vacuum cleaner
 - 2. Using a fire extinguisher, something like that
 - 3. Putting something
- Questions 2:
- What is a reason that can be found in your neighborhood. Why is each harmful to you, younger siblings or friends?
- _____
- _____
- _____
- Questions 3:
- Which can you find in your neighborhood? Choose all answers that are correct.
- 1. Vacuum cleaner
 - 2. Fire alarm
 - 3. Fire extinguisher
 - 4. Fire alarm
 - 5. Fire alarm
 - 6. Fire alarm
 - 7. Fire alarm
 - 8. Fire alarm
- Questions 4:
- Which can you find in your neighborhood? Choose all the answers that you think are right.
- 1. Fire alarm
 - 2. Fire alarm
 - 3. Fire alarm
 - 4. Fire alarm
 - 5. Fire alarm
 - 6. Fire alarm
 - 7. Fire alarm
 - 8. Fire alarm
- Questions 5:
- Which can you find in your neighborhood? Choose all the answers that you think are right.
- 1. Fire alarm
 - 2. Fire alarm
 - 3. Fire alarm
 - 4. Fire alarm
 - 5. Fire alarm
 - 6. Fire alarm
 - 7. Fire alarm
 - 8. Fire alarm
- Thank you for answering the questions!

Chapter 267

**REPORT TO CONGRESS ON TRAUMATIC BRAIN
INJURY IN THE UNITED STATES: UNDERSTANDING
THE PUBLIC HEALTH PROBLEM AMONG CURRENT
AND FORMER MILITARY PERSONNEL^{*}**

CDC, NIH, DOD, and VA Leadership Panel

PREFACE

Since the beginning of Operation Enduring Freedom (OEF) (Afghanistan) and Operation Iraqi Freedom (OIF), public health and health care-communities have become aware of the increased rates of traumatic brain injury (TBI) among active duty U.S. military personnel. Epidemiologic and clinical studies suggest that many of these military service-related injuries have serious long-term health and socioeconomic consequences.

In response to these public health and medical concerns, Congress passed the Traumatic Brain Injury Act of 2008 (*TBI Act of 2008*), which requires the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH), in consultation with the Department of Defense (DoD) and Department of Veterans Affairs (VA), to determine how best to improve the collection and dissemination of information on the incidence and prevalence of TBI among persons who were formerly in the military; and to make recommendations on the manner in which CDC, NIH, DoD, and VA can collaborate further on the development and improvement of TBI diagnostic tools and treatments. To that end, the CDC, NIH, DoD, and VA formed a Leadership Panel of experts with extensive experience in epidemiologic and clinical research, and in treating and managing TBI and its consequences.

This report presents the major findings and recommendations of the Leadership Panel and a review of relevant scientific literature and a thorough examination of current TBI-related activities and programs conducted by the four agencies/departments. It describes the public

^{*} This is an edited, reformatted and augmented version of a publication from the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) in collaboration with the Department of Defense (DOD) and the Department of Veterans Affairs (VA), June 2013.

health importance of military service- related TBI, recommends how to measure the magnitude of the health and socioeconomic impact of TBI and suggests ways in which the four agencies/departments can collaborate further on the development and improvement of TBI diagnostic tools and treatments.

LIST OF ACRONYMS

AFIP:	Armed Forces Institute of Pathology
AMS:	Army Medical Surveillance Activity
BRFSS:	Behavioral Risk Factor Surveillance System
BROS:	Blind Rehabilitation Outpatient Specialists
BTBIS:	Brief TBI Survey
BTF:	Brain Trauma Foundation
BTP:	Blast Tracker Program
CDC:	Centers for Disease Control and Prevention
CDMRP:	Congressionally Directed Medical Research Program
CIDNE:	Combined Information Data Network Exchange
CNRM:	Center for Neuroscience and Regenerative Medicine
DHHS:	Department of Health and Human Services
DHMIS:	Defense Health Information Management System
DMDC:	Defense Manpower Data Center
DoD:	Department of Defense
DVBIC:	Defense and Veterans Brain Injury Center
FIRP:	Federal Individual Recovery Plan
FRC:	Federal Recovery Coordinator
FRCP:	Federal Recovery Coordination Center
GCS:	Glasgow Coma Scale
HRSA:	Health Resources and Services Administration
IOM:	Institute of Medicine
JIEDDO:	Joint Improvised Explosive Device Defeat Organization
LOC:	Loss of consciousness
LRMC:	Landstuhl Regional Medical Center
MACE:	Military Acute Concussion Evaluation
MCS:	Millennium Cohort Study
MHS:	Military Health System
NCAT:	Neurocognitive Assessment Tool
NCHS:	National Center for Health Statistics
NCIPC:	National Center for Injury Prevention and Control
NCMRR:	National Center on Medical Rehabilitation Research
NDAA:	National Defense Authorization Act
NDSC:	National Data and Statistical Center
NHANES:	National Health and Nutrition Examination Survey
NHIS:	National Health Interview Survey
NHLBI:	National Heart, Lung, and Blood Institute

NIA:	National Institute of Aging
NIAAA:	National Institute on Alcohol Abuse and Alcoholism
NICHD:	Eunice Kennedy Shriver National Institute of Child Health and Human Development
NIDA:	National Institute on Drug Abuse
NIDRR:	National Institute on Disability and Rehabilitation Research
NIH:	National Institutes of Health
NIMH:	National Institute of Mental Health
NINDS:	National Institute of Neurological Disorders and Stroke
NINR:	National Institute on Nursing Research
OAFME:	Office of The Armed Forces Medical Examiner
OEF:	Operation Enduring Freedom
OIF:	Operation Iraq Freedom
OPD:	Outpatient department
PCS:	Post-concussive syndrome
PDHA:	Post-deployment health assessments
PH:	Psychological health
PHI:	Protected health information
PRC:	Polytrauma Rehabilitation Center
PTSD:	Posttraumatic stress disorder
QUERI:	Quality Enhancement Research Initiative
SLAITS:	State and Local Area Integrated Telephone Survey
SM:	Service member
SME:	Subject matter expert
SMs:	Service members
TBI:	Traumatic brain injury
TBIMS:	TBI Model Systems
TMDS:	Theater Medical Data Store
TSWG:	Technical Support Working Group
USAMRMC:	U.S. Army Medical Research and Materiel Command
USUHS:	Uniformed Services University of the Health Sciences
VA:	Department of Veterans Affairs
VCSA:	Vice Chief of Staff of the Army
VHA:	Veterans Health Administration
VHR:	Veterans Health Registry
VIST:	Visual Impairment Service Team
WARCAT:	Warrior Administered Retrospective Casualty Assessment Tool

GOALS OF THE REPORT

To respond to the mandate of the *TBI Act of 2008* and to accomplish the goals of this report, CDC, NIH, DoD, and VA formed a Leadership Panel comprising representatives from each of these four agencies/departments. These persons were researchers and investigators with extensive experience in TBI-related epidemiologic and clinical research and in treating

and providing rehabilitation for TBI survivors. To prepare their respective contributions to the report, members of the panel reviewed all current TBI-related activities and programs conducted by the four agencies/departments and relevant scientific literature.

This report represents the culmination of the Leadership Panel's deliberations and summarizes findings and recommendations. By sharing the results of this effort, CDC, NIH, DoD and VA aim to:

- **Raise Awareness:** Describe the public health importance of TBI among people currently or formerly in the military;
- **Improve Surveillance:** Recommend how to better measure the magnitude and impact of this condition in this population and the country; and
- **Strengthen Collaboration:** Suggest how the four agencies/departments can collaborate further on the development and improvement of TBI-related diagnostic and prognostic tools, treatment, management, and rehabilitation.

MEMBERS OF THE LEADERSHIP PANEL

Centers for Disease Control and Prevention

- **Victor G. Coronado, M.D., M.P.H., Executive Secretary**
Medical Officer
Division of Injury Response
National Center for Injury Prevention and Control
Centers for Disease Control and Prevention
4770 Buford Highway NE Atlanta, GA 30341
- **Vikas Kapil, D.O.**
Associate Director for Sciences
Division of Injury Response
National Center for Injury Prevention and Control
Centers for Disease Control and Prevention
Atlanta, GA 30333
4770 Buford Highway NE
Atlanta, GA 30341

National Institutes of Health

- **Beth Ansel, Ph.D.**
Program Director
National Center for Medical Rehabilitation Research
The *Eunice Kennedy Shriver* National Institute of Child Health and Human Development
National Institutes of Health
6100 Executive Blvd Room 2A03, MSC 7510

Bethesda MD. 20892-7510

- **Ramona Hicks, Ph.D.**

Program Director

National Institute of Neurological Disorders and Stroke

National Institutes of Health

Neuroscience Center, Room 2206

6001 Executive Blvd MSC 9525

Bethesda, MD. 20892-9525

- **Walter Koroshetz, M.D., Ph.D.**

Deputy Director

National Institute of Neurological Disorders and Stroke

National Institutes of Health

Building 31, Room 8A52

31 Center Dr. MSC 2540

Bethesda, MD. 20892

- **Michael Weinrich, M.D.**

Director

National Center for Medical Rehabilitation Research

The *Eunice Kennedy Shriver* National Institute of Child Health and Human Development

National Institutes of Health

6100 Executive Blvd Room 2A03, MSC 7510

Bethesda, MD. 20892-7510

Department of Defense

- **COL Jamie Grimes, M.D.**

National Director

Defense and Veterans Brain Injury Center, National Headquarters

1135 East-West Highway, Suite 6-100

Silver Spring, MD. 20910

- **COL Michael S. Jaffee, M.D.**

Pulmonary Clinic, Pulmonary Rehab (COPD), & Sleep Medicine

Wilford Hall Ambulatory Surgical Center
